B1 cells are a small subpopulation of B cells, with unique features that differ from the majority of mature B cells (Berland and Wortis, 2002). B1 cells mainly originate from the fetal liver and are found in the peritoneal and pleural cavities of mice (Baumgarth, 2011). In today, most of what is known about these cells comes from studies in mice.

B1 cells divided into B1a cells which expresses CD5 on the cell surface and B1b cells which do not (Vale et al., 2015). B1 cells are able to produce natural antibodies, mainly IgM, IgA and IgG3. In fact, B1 cells produce about 80% of natural IgM with low affinity, poly-specificity but high poly-reactivity and complement activation ability (Baumgarth et al., 2000).

In mice, they generate natural antibodies without infection (T cell-independent activation), secrete cytokines, defend against mucosal pathogens, uptake and present antigens to T cells during pathogen invasion (Baumgarth, 2011; Novaes e Brito et al., 2019).

Regulatory B cells

Regulatory B (Breg) cells represent the population of B cells that contribute to immunomodulatory processes and suppression of immune responses. Breg cell functions have been demonstrated in mice and humans in autoimmune diseases, cancer, infection and organ transplantation (Ray and Dittel, 2017; Karahan et al., 2017; Shen et al., 2016).

There are no unique surface markers that identify Breg cells (Silva et al., 2012). Therefore, there is still no consensus on definition and classification of Breg cells (Silva et al., 2012). First, the CD19⁺CD5⁺CD1d^{hi} B cell subset was found to function as suppressors of diseases in mice (Yanaba et al., 2008). Subsequently, the CD19⁺CD24^{hi}CD38^{hi} B cell subset was found to function as suppressors of diseases and inhibit the proliferation and function of proinflammatory cells in human blood (Blair et al., 2010). However, numerous Breg-cell subgroups with different phenotypes and effector functions are still described in mice and humans.

The main mechanism of Breg cells is through the anti-inflammatory cytokine interleukin 10 (IL-10) (Rosser and Mauri, 2015; Floudas et al., 2016). Breg cells also function by IL-10 independent mechanisms through cytokines such as IL-35, transforming growth factor (TGF)- β , and cell-to-cell contact. These cells regulate the immune system by many different mechanisms that are not fully elucidated. Furthermore, there is evidence that almost all B cell types can differentiate into Breg cell (Silva et al., 2012).

Flow cytometry examples

Burkitt lymphoma

Burkitt Lymphoma (BL) is a rare and aggressive form of Non-Hodgkin Lymphoma (NHL) that is usually found in extranodal sites or presenting as an acute leukemia (Ferry, 2006). And also, BL is recognized as a fast growing tumor. BL can be divided into three clinical variants: endemic, sporadic, and immunodeficiency-associated variants.

The diagnosis of BL is made as a result of the combined evaluation of morphological, immunophenotypic and cytogenetic findings. The characteristic immunophenotype of BL arises from mature B cells with germinal center cell differentiation (Kelemen et al., 2010).

In immunophenotypic evaluation of BL; BL cells are bright CD45, very large and mimic large lymphocytes. Tumor cells are positive for CD45. BL cells are positive for B-cell antigens such as CD19, CD20, CD22 and CD79a with a monoclonal light chain expression of kappa or lambda. CD10, CD38, CD43 and bcl-6 are also expressed. The blast markers CD34 and TdT, and bcl-2 are negative.

An example histogram/dot plots of BL are shown Fig. 6.

Mantle cell lymphoma

Mantle cell lymphoma (MCL) is a subtype of B-cell lymphoma and characterized by pregerminal center B cell proliferation within the mantle zone surrounding normal germinal center follicles of lymphoid tissues. Almost all cases show genetic abnormality t(11;14), which is resulting in overexpression of cyclin D1 protein. The clinical course is usually aggressive and the median survival is 3–4 years.

The initial gating dot plot identifies a predominant CD45 bright SSC low population consistent with lymphocytes. MCL cells are positive for pan-B-cell antigens CD19, CD20, CD22 and usually CD5 positive (rarely CD5 negative). CD10, CD23, bcl-6 are negative and FMC7 positive. And also, heavy chain (IgG, IgA and IgM) and light chain Ig (kappa or lambda) are moderately expressed.

An example histogram/dot plots of MCL are shown Fig. 7.

Fig. 7 Dual parameter dot plots useful in the diagnosis of Mantle cell lymphoma. R: lymphocytes; S: monocyte; T: granulocytes.

Glanzmann thrombasthenia

Glanzmann thrombasthenia (GT) is an autosomal recessive, inherited qualitative or quantitative platelet disease caused by deficiency or decreased function of the glycoprotein (Gp) IIb/IIIa complex in the platelet membrane. There are three subtypes which is determined by Gp IIb/IIIa level and varying in clinics. In this disease, most patients present with severe mucocutaneous bleeding at an early age. Diagnosis can be made using CD41 and CD61 monoclonal antibodies in flow cytometry examination.

Bernard-Soulier syndrome

Bernard Soulier syndrome (BSS) is a rare, autosomal recessive platelet dysfunction disease. It occurs as a result of the lack, absence or dysfunction of the glycoprotein Ib/V/IX complex, which is responsible for primary adhesion on the platelet surface (Diz-Küçükaya, 2013). Clinical findings are in the form of mucocutaneous bleeding (purpura, epistaxis, gingival bleeding, menorrhagia, gastrointestinal system bleeding) as in other platelet dysfunctions and rarely, life-threatening bleeding may occur (Lanza, 2006). And also, platelet counts vary depending on the presence of giant platelets (macrothrombocytopenia) (Andrews and Berndt, 2013).

FCM analysis shows normal binding with antibodies to CD41 (GP IIb) and CD61 (GPIIb), but defective binding with antibodies to CD42a (GPIX), CD42b (GPIb), CD42c (GP Ib) and CD42d (GPV) (Harrison et al., 2011).

Marginal zone lymphoma

Marginal zone lymphoma (MZL) is a heterogeneous and slow-growing group of B-cell NHL resulting from malignant transformation of marginal zone B cells (Bron et al., 2019). There are three main subgroups with variable clinics: extranodal, nodal and splenic MZL.

In immunophenotypic evaluation of MZL; the CD45 and SSC gate dot plot is used to identify different cell populations. MZL cells are positive for CD20, CD79a. CD5, CD10, CD23, CD43 are negative (Figs. 8–14).

Fig. 8 Glanzmann thrombasthenia with reduced level of both CD41 and CD61. J: Thrombocytes.

Acute B lymphoblastic leukemia

Acute B lymphoblastic leukemia (B-ALL) is characterized by the development of large numbers of immature lymphocytes and is also a clonal enlargement of lymphoid blasts in bone marrow, blood, or other tissues. Possible factors associated with ALL are radiation, viruses, cytotoxic chemotherapy and benzene, but in most cases the cause is unknown (Onciu, 2009).

In immunophenotypic analysis; CD19, CD22, CD79a, CD24, TdT are positive for B-ALL. CD10 is positive in common-ALL (CALLA +), cytoplasmic Ig is positive in pre-B-ALL and surface Ig is positive in mature B-ALL. Myeloperoxidase (MPO), a marker for myeloid lineage, is typically not expressed.

Apoptosis

Apoptosis is a tightly regulated biochemical process centered primarily around the caspases family of enzymes. With conjugated annexin V is a widely used reagent in the detection of apoptotic cells (Fleisher and Oliveira, 2019).

Sepsis

Sepsis is a major health problem that causes thousands of deaths worldwide each year and is largely under-recognized. Prevention, diagnosis and management of sepsis is a very important issue because the mortality rate is high (Reinhart et al., 2017). Therefore, early diagnosis and initiation of appropriate treatment are very important.

Currently used markers to evaluate septic patients immunophenotypically; CD64, CD16, CD16-56, CD11b and HLA-DR.

Fig. 9 Bernard Soulier Syndrome normal binding with antibodies to CD41 and CD61, but defective binding CD42b. R: Thrombocytes.

Cell cycle

We can detect cell populations at different stages of the cell cycle, such as G0/G1, S, and G2/M. We can also identify apoptotic cells (Bajgelman, 2019).

Conclusion

FCM has come a long way since the development of the first prototype. FCM has become readily available in clinical laboratories, with significant improvements in instrumentation. And day by day, it has started to be used in different fields of many branches of science. It plays an important role in the evaluation and understanding of complex diseases and in the longitudinal monitoring of treatments.

B cells are an important component of acquired immunity, responsible for the humoral immune response. These cells, which originate from the common progenitor cells in the bone marrow, continue their development in the secondary lymphoid organs and turn into plasma cells or memory B cells. Many mechanisms and signals are involved in the development and differentiation of B cells. Defects in developmental stage can lead to the formation of auto reactive B cells, malignancies and immunodeficiencies. Detection of dysfunctional B cells and defects, determination of their expression patterns, and investigation of therapeutic targets will help in the treatment of B cell-related diseases. Consequently, FCM has become a standard laboratory tool for the evaluation of hematopoietic cells and the identification of leukocyte populations and subsets. In addition, applications of FCM are used in many areas such as evaluating intracellular properties, characterizing apoptosis, evaluating changes in the cell as a result of stimulation, and identifying antigen-specific T cells. Thus, FCM has recently become a frequently used instrument as a diagnostic and research method in B cell diseases.

Fig. 14 DNA content cell cycle analysis (upper dot plots show normal cell cycle and DNA content. Lower dot plots show peripheral blood mononuclear cell [PBMC]). The histograms are gated to exclude debris and doublets. For DNA, doublets are detected by collecting peak versus integrated signals. In the dot plots on the right, we can distinguish between the G0/G1, S, and G2/M phases of the cell cycle and apoptotic cells.

The applications of this technology are developing significantly and new applications will emerge thanks to the rapidly developing technology. In this way, we can expect to be able to understand all the knowledge of B cell biology in the near future with the use of FCM.

Introduction

T cell function assays involve the application of diverse techniques in order to decipher adaptive cell-mediated immune responses for diagnostic as well as for research purposes. T cell responses can be assessed by means of proliferative potential, cytokine secretion profile, immunophenotyping and subtype characterization, in bulk or antigen-specific T cell populations. High-throughput and robust newer methods enable the detection of immune responses even at the single-cell level and provide unprecedented insight on the complex mechanisms that mediate T cell responses and interactions. This abundance of options and possibilities renders the selection of the most suitable assay in a specific context challenging, and therefore require the deep understanding of the special characteristics, applications, and limitations of each method (Table 1).

Antigen presentation, through the interaction of Major Histocompatibility Complex (MHC) I or MHC II molecules with the T cell receptor, induces T cell proliferation and differentiation from naïve to effector and memory cells. This antigen-specific process pertains both normal host defense mechanisms, e.g., against pathogens or cancerous cells, as well as pathological immune states, such as autoimmunity and allergy. T cells are traditionally divided into two main subtypes: helper (CD4⁺) T cells and cytotoxic (CD8⁺) T cells. CD4⁺ T cells can be further analyzed into the T helper (Th) 1 and Th2 subsets, and the more recently discovered Th17, Th22, Th9 and follicular Th (Tfh) subsets. Regulatory T cells (Tregs) also play an important role promoting immune tolerance against self-antigens and providing protection against the deleterious effects of excessive immune responses.

The first part of this chapter provides an account of the most widely used T cell function assays, including the evaluation of proliferation, cytokine secretion, cytotoxicity and surface-marker expression, as well as single-cell analysis methods. The application of these assays in infectious diseases, transplantation, cancer, primary immunodeficiencies, allergy and autoimmunity is discussed in the second part of this chapter.

Table 1 Advantages and disadvantages of usually applied T cell function assays.

Assay	Advantages	Disadvantages
<i>Proliferation assays</i>		
[³ H]-thymidine incorporation	– Well validated	– Time consuming – Radioactive reagents – Endpoint assay
BrdU incorporation	– Non-radioactive – Capacity for <i>in vivo</i> experiments	– Requires DNA denaturation and membrane permeabilization
EdU incorporation	– Non-radioactive – Better reproducibility	
Fluorescent dye dilution	– Does not require DNA denaturation – Allows immunophenotyping – Can be used in combination with ICS or surface markers	– Cytotoxicity of dyes – Loss of dye intensity with multiple division cycles
Ki 67	– Good sensitivity – Suitable for multiparametric FC	– Does not specify number of cell divisions
<i>Cytokine-based assays</i>		
ELISA	– Widely available	– Cannot inform about cytokine producing cells – One cytokine per assay – Large sample volumes required for multiple cytokine detection
Cytometric bead array	– Multiple cytokines detection in one run (up to 100 targets) – Automated – Requires small sample volume	– Cannot inform about cytokine producing cells – Endpoint assay
ELISpot	– Quantitative and qualitative detection of cytokine-secreting cells – Extremely sensitive/detect even very low frequency T cells	– Cannot inform about the phenotype of cytokine producing cells (only their number) – Investigation of limited number of parameters
FluoroSpot	– Detection of up to four targets per assay	
ICS-FACS	– Parallel detection of multiple cytokines – Can be combined with other assays for extensive T cell phenotyping	– Endpoint assay due to chemical fixation of cells – Less sensitive than ELISpot
Cytokine secretion assay	– Isolation of live cells – Suitable for rare cell populations	
<i>Cytotoxicity assays</i>		
<i>a. Indirect</i>		
⁵¹ Cr release	– Sensitive	– Costly – Handling of radioactive compounds – High inter-assay variability – Background “noise”
CFSE dilution	– Sensitive – FACS based, allows phenotypic analysis of T cells	– CFSE cytotoxicity
7-AAD/PI	– Sensitive – FACS based, allows phenotypic analysis of T cells	
LDH release	– Widely available	– Low sensitivity/specificity
<i>b. Direct</i>		
CTL-ELISpot	– Quantitative and qualitative detection of cytokine-secreting cells – Extremely sensitive/detects even very low frequency T cells	– Cannot inform about the phenotype of cytokine producing cells
ICS-FACS (GrB/perforin)	– Phenotypic information available – “Single-cell” level information	– Cytokine-dependent – Endpoint assay
CD107a/FasL	– Phenotypic information available – “Single-cell” level information	
MHC-I tetramer staining	– Phenotypic information available – “Single-cell” level information	– Requires prior knowledge of epitope or HLA type
Activation induced markers (AIM)	– Cytokine-independent – Detection based on antigen-specificity	
<i>Single-cell analysis</i>		
Peptide-MHC polymer staining	– Detects all antigen-specific T cells, not only effector cells	– Requires prior knowledge of epitope or HLA type
Flow cytometry	– Easy to use & widely available	– Large panels require good compensation – Limited amount of information compared to CyToF & RNA-seq
CyToF	– No compensation needed – High variety of markers allows thorough phenotyping	– High cost – Endpoint assay – Limited availability
RNA-seq	– No compensation needed – Highest amount of information	– High costs – Endpoint assay – Limited availability (but increasing)

T cell function assays

Proliferation assays

Proliferation assays provide information about the extent of T cell response to specific antigenic or mitogenic stimuli. Historically, DNA incorporation of radio-labeled nucleoside analogs has been considered the “gold standard” for the assessment of T cell proliferation, but its use has since declined in favor of newer techniques.

[³H]-thymidine incorporation

This well-validated semiquantitative assay uses tritiated [³H]-thymidine incorporation into nascent DNA synthesized during the S phase of cell cycle, to assess T cell proliferation after antigen stimulation (Romar et al., 2016; Saade et al., 2012). Peripheral blood mononuclear cells (PBMCs) (or any other sample containing T cells and antigen-presenting cells), are cultured in wells, in the presence of the antigen of interest for 2 to 7 days, depending on the applied protocol, and then pulsed with the radioactive material. The incorporated radioactivity is measured up to 24 h after the addition of [³H]-thymidine by a scintillation beta counter and T cell proliferation is usually expressed as a stimulation index (SI), which is the ratio of the mean cell response in the antigen containing wells to that of control wells (Knutson et al., 2006). The main disadvantages of tritiated thymidine incorporation assay include safety issues that arise due to handling of radioactive material, inability to provide information on the phenotype, function and division history of individual cells, the need for prolonged incubation time and cumbersome steps, and the inherent variability of the method. Moreover, it is an endpoint assay as viable daughter cells cannot be retrieved for further characterization (Romar et al., 2016; Wallace et al., 2008). For these reasons, this technique has been largely replaced by flow cytometry-based assays of proliferation.

BrdU incorporation

An alternative non-radioactive thymidine analog, 5-brom-2'-deoxyuridine (BrdU), has been used for labeling proliferating T cells, *in vitro* and *in vivo*. BrdU incorporation in the DNA can be detected with a BrdU-specific monoclonal antibody, that can be subsequently traced by a fluorescent tag. BrdU presence is measured by means of flow cytometry or fluorescence microscopy. Also, it allows for *in vivo* assessment of cell proliferation in experimental animals, as it is stably integrated into the DNA after injection or digestion (Rothaeusler and Baumgarth, 2007). Although BrdU assay can be used simultaneously with other cell markers, it requires DNA denaturation and both cell and nucleus membrane permeabilization steps, thus limiting multiparametric analysis by flow cytometry. To overcome these drawbacks, a newer nucleoside analog, 5-ethynyl-2'-deoxyuridine (EdU) has been introduced that does not require harsh DNA denaturation processes (Poujol et al., 2014; Sun et al., 2016). Furthermore, EdU labeling shows better reproducibility and greater signal-to-noise ratio than the BrdU assay (Flomerfelt and Gress, 2016).

Fluorescent dye dilution assays

Fluorescent dyes diffuse easily through the cell membrane and bind covalently with amino groups on cytoplasmic macromolecules (Dey et al., 2019). The amount of dye present in each cell progressively decreases after each cycle of cell division and this reduction in fluorescent intensity can be quantified by flow cytometry (Saade et al., 2012). The most extensively used dye is the carboxy-fluorescein succinimidyl ester (CFSE), which generates a green fluorescent signal (Romar et al., 2016). Alternative dyes include cell trace violet (CTV), violet proliferation dye 450 (VPD-450), and CFSE derivative Oregon Green (Ten Brinke et al., 2017). Dye dilution assays are suitable for the further phenotypic characterization of dividing cells, allowing the detection of various surface markers and/or intracellular cytokines (Phetsouphanh et al., 2015). However, high concentrations of these dyes are cytotoxic and could impair both cell proliferation and expression of activation markers. Furthermore, CFSE allows for the detection of up to approximately 8 cycles of cell divisions due to the loss of fluorescence intensity with each division (Saade et al., 2012). Crucially, dye dilution assays, in contrast with the tritium-labeled thymidine assay, can be used to determine the frequency of antigen-specific T cells in the original population (Ten Brinke et al., 2017).

Ki67 expression

Ki67 is a nuclear protein expressed in all actively proliferating cells and during the phases G₁, S, G₂ and M of the cell cycle, whereas is undetectable in resting cells (G₀) (Lašćovička et al., 2016). It is a very sensitive assay for the assessment of antigen-specific T cell proliferation and it has been found to correlate well with [³H]-thymidine and BrdU incorporation assays, as well as with the CFSE dye dilution assay (Lašćovička et al., 2016; Soares et al., 2010). Ki67 staining can be followed by multiparametric flow cytometry for the delineation of T cells. However, Ki67 expression assay cannot provide information about the number of divisions that the cells have gone through, thus not allowing the estimation of the frequency of precursor specific cells (Soares et al., 2010).

Cytokine-based T cell assays

Cytokines are signaling molecules responsible for the orchestration and regulation of immune responses. Some of the most widely used assays for the assessment of T cell function involve the qualitative and quantitative measurement of cytokine secretion from stimulated T cells. Cytokine profiling provides information regarding the kind of elicited immune response (e.g., Th1, Th2, Th17) and the activation of antigen-specific T cells in bulk cell populations as well as on the single-cell level.

Enzyme-linked immunosorbent assay (ELISA)

ELISA is a readily available and easy to perform technique that enables the detection and quantification of various cytokines. Suitable clinical samples include PBMC supernatant and whole blood, but other fluids and tissue lysates can be used for research purposes. The detection of interferon (IFN)- γ , tumor necrosis factor (TNF)- α and interleukin (IL)-2 cytokines usually marks the presence of Th1 response, whereas other combinations are used to define other T cell subsets, such as Th2 (IL-4, IL-5, IL-13), Th17 (IL-17, IL-21, IL-22) and Treg (tumor growth factor [TGF]- β , IL-10). Unfortunately, this method cannot provide any information regarding the individual cell populations producing the detected cytokines. Moreover, ELISA is able to measure only one cytokine per assay, thus requiring large sample volumes and labor-intensive procedures.

Cytometric bead array

To enable the simultaneous detection of multiple targets and to reduce time, labor and cost, multiplex bead-based methods have been developed. Polystyrene microspheres, internally dyed with two or three distinct fluorochromes and covered with target specific antibodies can be processed by a flow cytometer, allowing the quantification of multiple cytokines in serum or cell culture supernatants (Graham et al., 2019). This automated, high-throughput assay requires only a small sample volume and has a good correlation and higher sensitivity than ELISA (Saade et al., 2012). The most widely used, commercially available form of cytometric bead array is the Luminex™ platform that allows for the detection of up to 100 targets at once. Despite these advantages over ELISA, multiplex assays also cannot provide information about the nature of cytokine-producing cells and are insufficient for the detection of low-frequency antigen-specific T cells.

ELISpot and FluoroSpot

Enzymed-linked immunospot assay (ELISpot) has been applied for the quantitative and qualitative detection of cytokine-secreting cells. The assay involves the culture of PBMCs in the presence of an antigen in wells coated with anti-cytokine antibodies. Antigen specific cells secrete the cytokine of interest, which then binds to capture antibodies. After washing the cells away, cytokine production can be visualized as colored spots by enzymatically labeled antibodies interacting with a chromogenic substrate. The size and intensity of each spot, assessed by a specialized ELISpot reader, correlate with the amount of cytokine secreted on the single-cell level. ELISpot is extremely sensitive and is ideal for the detection of the very low frequency antigen-specific T cells, with or without the inclusion of in vitro expansion steps. On the downside, this method is able to assess only one or two analytes per assay and does not provide any information on the phenotype on the cytokine-secreting cells. However, FluoroSpot, a newer design of the assay using fluorochrome-conjugated detection antibodies and an automated fluorescence reader, allows the detection of up to four cytokines. Moreover, washed cells can be recovered and restudied with subsequent assays, allowing for their further characterization.

Intracellular cytokine staining (ICS)

A different approach for the assessment of cytokine secretion from antigen-specific T cells is the intracellular cytokine staining assay, typically coupled with fluorescence activated cell sorting (FACS). The technique involves the use of Golgi inhibitors (e.g., brefeldin A or monensin) which inactivate granule secretion and lead to intracellular retention of produced cytokines and other proteins (Phetsouphanh et al., 2015). Staining with fluorescent-labeled anti-cytokine monoclonal antibodies is performed after cell fixation and permeabilization (Lovelace and Maecker, 2018). Multiple cytokines can be detected at the same time as well as other intracellular and cell surface markers of differentiation, function and proliferation (Lovelace and Maecker, 2018; Saade et al., 2012), thereby enabling the extensive phenotyping and subset characterization of antigen-specific T cells. These properties of multi-parametric ICS enable the detection of polyfunctional T cell phenotypes (Smith et al., 2015). On the other hand, despite the advantages of this assay, the required step of T cell chemical fixation does not permit the retrieval of live cells for further analysis (Phetsouphanh et al., 2015). Also, ELISpot seems to be more sensitive than ICS for the detection of very low frequency T cell responses (Karlsson et al., 2003; Saade et al., 2012).

Cytokine secretion assay

Cytokine secretion assay is based on the formation of an anti-cytokine antibody matrix on the cell surface. After polyclonal or antigen-specific activation, PBMCs are labeled with bispecific antibodies that bind to a cell surface marker (i.e., CD45) and the cytokine of interest (Campbell et al., 2011; Rezk et al., 2020). Upon secretion, cytokines are captured by the bispecific antibodies on the cell surface and are identified with another fluorochrome-conjugated cytokine-specific antibody for flow cytometric analysis (Saade et al., 2012). Another option is to label the captured cytokine with antibodies conjugated with super-paramagnetic particles followed by magnetic activated cell sorting (MACS) (Assenmacher et al., 2002; Campbell et al., 2011).

Cytotoxic T lymphocyte assays

Cytotoxicity of cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells supply an important mechanism in the defense against infection by viruses or intracellular-bacteria, and in anti-tumor immunity. The measurement of their lytic capacity provides useful insights in studying the properties of these cells. Lytic capacity can be studied in two ways: either indirectly by e.g. measuring the release of reporter molecules of targeted cells like in the classical ^{51}Cr release assay (Dunkley et al., 1974), or by assessment of cell death and/or apoptosis of targeted cells. Direct methods would include the measurement of molecules, which are directly involved in the lytic process of targeted cells and are provided by CTLs and NK cells e.g. the release of Granzyme B (GrB) and Perforin.

Indirect measurement of the effector function

In the ^{51}Cr release assay, target cells are loaded with an antigen of interest and labeled with ^{51}Cr . Loaded and labeled cells are then mixed and incubated in different ratios with effector cells. Mixing of target with effector cells should result in the lysis of target cells and subsequent release of ^{51}Cr into the cell supernatant, which can then be measured by a γ counter. Today, similar principles are used and combined with the power of flow cytometry (FACS). Cells are labeled with non-radioactive fluorescent dyes like CFSE (McGinnes et al., 1986) in combination with dyes for the assessment of cell death (Kandarian et al., 2017; Kim et al., 2020). A decrease in the intensity of CFSE labeled cells indicates increased cytotoxic activity of CTLs or NK cells. Other approaches use only dyes like 7-amino-actinomycin (7-AAD) and propidium iodide (PI), and directly measure ongoing apoptosis (Kim et al., 2007). Similar to the release of radioactive ^{51}Cr or to the use of fluorescent dyes like CFSE, the release and activity of enzymes can be used for the detection of cell lysis (Weyermann et al., 2005). The principle that governs these assays is the assessment of active enzymes, which are released from the cytosol into the cell culture supernatant upon lysis of the target cells. The functional properties of these enzymes are then used as an indicator for ongoing cell lysis. A representative example is the LDH enzyme-release assay (Korzeniewski and Callewaert, 1983). LDH is quickly released into the cell culture supernatant when the cell membrane is damaged during apoptosis. Subsequently, the supernatant is collected and incubated in the presence of NADH (produced during the oxidation of lactate to pyruvate by LDH), and an indicator, such as tetrazolium salt, that is reduced into a measurable red, water-soluble formazan-class dye (Kumar et al., 2018; Smith et al., 2011). A disadvantage of LDH release assay is that it does not differentiate between apoptosis and other forms of cell death. On the other hand, spontaneous release of LDH during the incubation period in comparison to that of ^{51}Cr is significantly lower (Korzeniewski and Callewaert, 1983).

Direct measurement of effector function

For the direct measurement of effector function of CTLs or NK cells, one can employ a variety of different methods. One option is to measure cytotoxic molecules by ELISpot. As previously described, ELISpot provides certain advantages and disadvantages over ELISA. ELISpot provides the possibility to measure effector molecules like IFN- γ or GrB in response to different stimuli e.g. virus peptides and could thus provide a means for the investigation of the effector function of CTLs and NK cells (Shafer-Weaver et al., 2003). Another option is to investigate effector function by FACS (Kim et al., 2007). FACS allows the investigation of different cell populations at once. By using the right labeling, NK cells and CTLs could be investigated in a single panel. Cells need to be stimulated ex vivo and the transport of granules containing GrB and Perforins needs to be inhibited by the use of the right inhibitors e.g. Brefeldin A, which blocks the transport from the Golgi apparatus to the cell surface (Letsch and Scheibenbogen, 2003). Similar stimulation can also be employed to investigate CD107a (Betts and Koup, 2004), which is another marker of degranulation and therefore indicates cytotoxic activity (Aktas et al., 2009), and could be combined with FasL (CD178), which mediates cell death by interacting with FasR (CD95) (Arase et al., 1995). Additionally, FACS provides the possibility to investigate the specificity of CTLs to certain antigens, as MHC class I tetramer staining of the T cell receptor would be possible (Xu and Screaton, 2002).

Activation-induced markers assay

Cytokine-based assays cannot account for the full repertoire of T cell responses after stimulation, as different T cell sub-populations are characterized by low frequency and functional heterogeneity. Activation-induced markers (AIM) assay is a cytokine-independent method for the detection of markers expressed on the cell surface following T cell receptor stimulation by a peptide-MHC complex. In contrast with intracellular cytokine staining, the AIM assay does not require cell fixation and permeabilization, thereby enabling the isolation of viable antigen-responsive T cells for further downstream applications (Elias et al., 2020).

Multiple markers have been investigated for the isolation of antigen-specific T cells. CD25 and CD69 are important T cell activation markers, but their lack of specificity necessitates the use of additional markers (Elias et al., 2020). The most widely applied combinations are CD25 (IL-2R α) /CD134 (OX40) and CD69/CD40L (CD154) for the isolation of antigen-specific CD4 $^{+}$ T cells, and CD107a/CD137 (4-1BB) for CD8 $^{+}$ T cells (Chattopadhyay et al., 2005; Frentsch et al., 2005; Wolff et al., 2007). CD25/OX40 is a global marker identifying all Th1, Th2, Th17, Tfh and Treg antigen-specific T cells. PD-L1, another activation-induced marker, in combination with OX40 can be used for the detection of all antigen-responsive T cells, excluding the Treg subpopulation, whereas 4-1BB $^{+}$ /CD40L $^{-}$ signature characterizes antigen-responsive CD4 $^{+}$ Tregs (Elias et al., 2020; Reiss et al., 2017; Schoenbrunn et al., 2012).

AIM assays are valuable for the detection of extremely difficult to isolate antigen specific cells, such as Tfh cells, which are underdetected in cytokine assays. Magnetic pre-enrichment can be used to collect a high number of low frequency T cells for further analysis, further increasing the sensitivity of the technique (Bacher et al., 2013). As with ICS, a problem with the AIM assay is the background caused by bystander activation that can limit the specificity of the method depending on the combination of markers used (Bowyer et al., 2018).

Suppression assays**Treg suppression assays**

Regulatory T (Treg) cells are responsible for the preservation of immune homeostasis and self-tolerance, controlling the expansion, activation function of effector T (Teff) cells. To produce these effects, Treg cells competitively consume IL-2, provide Teff cells with the inhibitory molecule cAMP, inhibit dendritic cells and promote the differentiation of Teff to Treg cells. Treg suppression assays

measure the ability of Treg cells to suppress the proliferation of antigen-responding CD4⁺ T cells *in vitro*. To assess their suppressive ability, a titrated amount of Tregs is cocultured with a specific number of antigen-specific T cells, and subsequently a proliferation assay, such as [³H]-thymidine incorporation or CFSE staining coupled with flow cytometry, is applied. Flow cytometry analysis permits the calculation of proliferation index (average number of divisions in the population), percentage of dividing cells, and division index (average number of divisions of a cell in the starting population). Moreover, flow cytometry allows simultaneous analysis for cell surface activation-induced markers and intracellular cytokine staining. Treg suppression assay may also be used in combination with IFN γ and TNF α detection in supernatant, as Tregs lead to robust suppression of these cytokines.

Viral inhibition assay

Viral inhibition assays have been developed in HIV research to address the failure of classical cytokine assays, such as IFN γ -ELISPOT and ICS, to predict the *in vivo* effectiveness of vaccine candidates (Pannus and Vanham, 2019; Spentzou et al., 2010). The method involves the coculture of activated, superinfected CD4⁺ T cells (target cells) with stimulated CD8⁺ T cells (effector cells), and enables the direct quantification of CD8⁺ T cells suppressive potential *ex vivo* (Slichter et al., 2014). Measurement of viral p24 in supernatant with ELISA or detection of intracellular gag with flow cytometry can be used for the quantification of viral replication in target cells alone and in coculture. The difference in viral replication represents the viral inhibitory activity of CD8⁺ T cells.

Single-cell analysis

Since the first development of flow cytometers in 1968/69 (Osborn, 1971), the technology of single cell analysis has made huge progress. The most commonly used method today is flow cytometry, but other methods have emerged, such as cytometry by time of flight (CyToF) or other single-cell analyzing methods which use beads linked to a barcode sequence and the mRNA of a gene of interest, which can later be identified using sequencing methods. Two manufactures using the latter method are Becton, Dickinson and Company (BD) with their Rhapsody™ or 10 $\times$ genomics with their Chromium™ instruments. Single-cell analysis is a powerful tool for immune-phenotyping. With recent developments in single-cell analysis, it is now not only possible to map the expression of surface or intracellular proteins, but also to make genome-wide expression studies in different cell populations at the same time.

The power and limits of flow cytometry

With flow cytometry already being in use for half a century, the method still has the potential for further improvement. Indicatively, recent advancements include the capability to measure up to 28 different fluorophores simultaneously, thus reaching a similar range of possibilities as with CyTOF instruments (Brummelman et al., 2019). As previously mentioned, flow cytometry can be applied in a variety of ways. Flow cytometry can be used to investigate different properties of cells and has a broad range of applications ranging from functional investigations to “simple” immunophenotyping of tissues using extra- and intracellular markers (Baumgarth and Roederer, 2000). By investigating different cell types, flow cytometry also provides the ability to use intracellular staining to look at cell signaling molecules e.g., p-ERK (Schmidt et al., 2018), and can thus provide insights into molecular pathways (Krutzik et al., 2004; Schulz et al., 2007). Moreover, peptide specific T cells can be identified using the power of fluorescently labeled peptide-bearing tetra- or pentamers (Newell et al., 2013; Rubio et al., 2003; Vollers and Stern, 2008). One of the biggest advantages is that flow cytometry offers the possibility to sort and isolate these labeled cells, which can then be used for further analysis (Bonner et al., 1972; Orfao and Ruiz-Argüelles, 1996; Pahl-Seibert et al., 2005). However, there are also limitations to the method, as spectral overlap of fluorescently labeled antibodies and autofluorescence need to be taken into account, and panels have to be built and compensated accordingly (Brummelman et al., 2019).

CyToF, a replacement for flow cytometry?

More recently, CyToF has emerged as a new method for identifying populations of cells. CyToF is also based on labeling targets of interest with molecular probes, such as antibodies. However, in this case, probes are not labeled with fluorescent dyes but rather with metal isotopes that emit a sharp signal, providing thus a major advantage over classic flow cytometry: the lack of spectral overlap. However, in contrast to flow cytometry, the cells are atomized and ionized during measurement and consequently cannot be retrieved for further analysis. Due to the sharp peak that is produced by the metal isotopes, CyToF theoretically provides up to 120 detection channels and a broader capability for immunophenotyping (Mora et al., 2014). Direct comparison of flow cytometry versus CyToF data has revealed that CyToF yields analogous quantification results of cell lineages (Gadalla et al., 2019). Similar experiments have been conducted measuring phosphorylated signal transducer and activator of transcription 3 and 5 (pSTAT3 and pSTAT5) for the assessment of intracellular signal transduction. In these experiments, data provided by CyToF correlate highly with those provided by flow cytometry (Mora et al., 2014). A similar experimental set-up has been used for a time-course analysis of STAT1, STAT3 and STAT5 phosphorylation in response to kinase inhibitors in PBMCs (Bodenmiller et al., 2012). Thus, when no further cell analysis is required, CyToF provides a powerful tool to simultaneously analyze different groups of cells and intracellular events on the protein level.

Single-cell RNA sequencing

Single-cell RNA sequencing (scRNA-seq) is another method which provides the possibility to characterize different sets of immune cells. As with CyToF, the cells are not retrievable after analysis and cannot be used for downstream assays, as they are lysed during

processing in order to access the transcriptome (Zhang et al., 2019). However, scRNA-seq can be combined with upstream bead-based cell isolation or FACS in order to enrich cells of interest, which can subsequently be analyzed to achieve the transcriptomic profile of particular cell populations on the single cell level. There are many available methods presented elsewhere (Stuart and Satija, 2019). Three of these methods are Smart-Seq2, BDs Rhapsody™ or the Chromium™ instruments from 10 × genomics. All these methods work on a similar principle where large cDNA libraries are generated from the mRNA profile of a single cell.

The Smart-Seq2 offers only the possibility to access the transcriptome, while surface markers cannot be analyzed and the single cell suspension has to be obtained using a different method (Picelli et al., 2013, 2014). The Rhapsody™ and Chromium™ instruments provide the ability to achieve both a single cell suspension and the investigation of other parameters, including, for example, cell surface markers, while also analyzing the transcriptome (Shum et al., 2019). The method of producing single cell suspension differs between the two instruments. While BD uses a system based on microwells and barcoded beads (Shum et al., 2019), the Chromium™ is based on a microfluidics system, where single droplets contain a single cell (Wang et al., 2021; Zhang et al., 2019). Both, however, work with the same principle of capturing the information of surface molecule expression. Moreover, these methods use antibodies that are linked to a specific nucleotide sequence. This allows the identification of these antibodies after sequencing, and thereby allows to build antibody panels similar to those seen in FACS, without the need for compensation.

Applications

The vast majority of the assays employed for the functional investigation of T cells are used primarily within research settings. There are only a few indications for their use in routine diagnostic assessment, namely for the diagnosis of tuberculosis and cytomegalovirus infection, as well as for the investigation of primary immunodeficiencies. The introduction of these assays into clinical practice has been challenging due to their complexity and cost, the need for specialized personnel and equipment, the high degree of inter-laboratory variability, and the difficulty to define clinically meaningful cut-off values. However, they have been indispensable tools for the comprehensive understanding of immune responses in health and disease, the development of new treatment strategies and the evaluation of therapeutic and/or preventive interventions.

Infectious diseases

T cell function assays have been widely applied in the field of infectious diseases, promoting the in-depth understanding of complex immune responses against various pathogens, the diagnosis of viral and microbial infection, and the evaluation of vaccine effectiveness.

Humoral immunity investigations, though easy and inexpensive to perform, are not sufficient to fully comprehend the diverse immune responses against infection. This has been the case particularly for certain viral and intracellular pathogens. Interestingly, robust T cell immunity has been detected in convalescent SARS-CoV-2 patients, even after the waning of serum specific antibodies, suggesting that cellular immunity may exist independently of antibody responses (de Candia et al., 2021). Antigen-specific T cell profiling regarding proliferation, cytokine secretion, activation, phenotype and function can provide insight into the pathogenicity, chronicity development and distinctive features of various infections. T cell function assays have also helped to elucidate the complex and catastrophic immune responses during sepsis, sepsis-induced immunoparalysis and cytokine storm (Martin et al., 2020).

IFN γ release assays (IGRA), based on ELISA or ELISpot techniques, have been implemented to overcome the drawbacks of tuberculin skin test (TST) that is used for the diagnosis of *Mycobacterium tuberculosis* (MTB) infection for over a century. The need for a new diagnostic test was dictated by the existing limitations in TST sensitivity and specificity, due to false negative results observed in immunosuppressed and HIV-infected individuals and false positive results caused by previous Bacille Calmette-Guérin (BCG) vaccination. ELISA-based QuantiFERON-TB assay (QFT) identifies *in vitro* antigen-specific T cells that secrete IFN γ in the presence of MTB peptides, the early secreted antigenic target 6 (ESAT6), the culture filtrate protein 10 (CFP10) and the TB7.7 antigen. T.SPOT-TB is an IFN γ -ELISPOT assay that also detects antigen-specific IFN γ production as a response to T cell stimulation by ESAT6 and CFP10. Because antigens contained in the BCG vaccine are different from those used in IGRAs, previous vaccination does not yield false positive results.

Assessment of T cell immune responses is of utmost importance in the development of new vaccines against pathogens for which humoral immunity alone does not offer considerable protection, such as viral and intracellular infections (e.g., HIV, malaria, TB, SARS-CoV-2, Ebola) (Saade et al., 2012). ELISpot and ICS (Streeck et al., 2009; Voss et al., 2018), as well as MHC-peptide tetramer and increasingly single cell analysis (Reeves et al., 2018), have been used extensively in vaccine studies for the detection of robust T cell responses, but *in vitro* effectiveness has not always been accompanied by vaccine success *in vivo* (Fitzgerald et al., 2011). Assays detecting cytotoxic T lymphocyte responses also play an important role for the assessment of protective immunity produced by candidate vaccines, especially against HIV and TB.

Transplantation

Solid organ transplantation (SOT) and hematopoietic stem cell transplantation (HSCT) greatly affect the immune system and its ability to fight infection. T cell assays have been used to monitor the immune status of the patients undergoing these procedures, to assess the risk of opportunistic infections due to immunosuppression, such as Cytomegalovirus (CMV), Epstein-Barr virus (EBV) and BK virus (BKV), and to evaluate the threat of graft rejection.

Due to the grave consequences of CMV reactivation in individuals undergoing transplantation, and particularly in allogeneic HSCT recipients, immune monitoring with assays that detect IFN γ secretion from CMV-specific CD8 $^{+}$ T cells has been proposed to guide pre-emptive treatment and management of CMV infection, in conjunction with CMV viral load measurement (Ljungman et al., 2019). IFN γ ELISPOT and ELISA-based QuantiFERON-CMV have both been successfully investigated in this context (Calarota et al., 2015). EBV latent infection may cause post-transplant lymphoproliferative disorders (PTLD) in immunosuppressed graft recipients, therefore monitoring EBV activity and tailoring immunosuppressive treatment accordingly is detrimental. Assessment of EBV-specific T cell responses with IFN γ -ELISPOT, ICS or pMHC multimer staining, when added to standard EBV viral load measurement, improves the ability to identify patients at risk and to monitor treatment efficacy (Calarota et al., 2015; Tischer et al., 2014). Another opportunistic infection affecting patients with a kidney transplant is BK polyomavirus reactivation, followed by nephropathy and graft dysfunction. In this case, the presence of detectable antigen-specific T cell responses by ELISpot correlates with the presence of functional antiviral immunity, and with the resolution of BK virus nephritis (Chakera et al., 2011). Finally, adoptive immunotherapy with the administration of virus-specific T cells derived from the patient, the donor or a third party, has been evaluated for the prophylaxis against and the resolution of multiple viral infections in transplant recipients. pMHC multimer technology as well as activation markers have been applied for the production of single- or multipathogen-specific T cell clones against CMV, EBV and Adenovirus (Khanna et al., 2011; Stemberger et al., 2014).

Another caveats in organ transplantation are the acute and chronic graft rejection. The best tactic to avoid such a dire consequence involves the selection of well tolerated organs by the host's immune system. Apart from human leukocyte antigen (HLA) matching between donor and recipient, another approach is the detection of alloreactive T cells by functional assays. These include proliferation assays to determine clonal size, T cell cytokine secretion with or without flow cytometry phenotyping, and intracellular ATP measurement (Anthony et al., 2012). Donor-specific IFN γ -ELISpot has been extensively studied for its ability to predict allograft rejection, with promising results (Montero et al., 2019). Intracellular cytokine staining followed by flow cytometry has the advantage of allowing the identification of cytokine-producing T cell subsets (Millán and Brunet, 2016).

Cancer

T cells, as part of the adaptive immune system, play a pivotal role in cancer immunology, ranging from tumor cell recognition, targeting and destruction, to cancer therapeutics and treatment monitoring. Cancer immunotherapy applications exploit and expand on the inherent immune system ability to fight tumor cells. Currently, cutting-edge techniques involving functional, molecular and antigen-specific T cell characterization and manipulation are deployed in adoptive T cell therapy, immune checkpoint blockade, and anti-tumor vaccine development.

Adoptive T cell therapy is based on the production of a tumor-specific T cell clone through either antigen stimulation in vitro or genetical engineering of T cells to express highly relevant T cell receptors (TCRs) or chimeric antigen receptors (CARs). Another approach is the non-specific in vitro expansion of naturally existing tumor-infiltrating lymphocytes (TILs) (Perica et al., 2015). This procedure is followed by the reinfusion of these cells into the body to enhance anti-tumor immune response. These approaches, though effective in vitro, do not always result into actual tumor regression. Cancer microenvironment promotes immune tolerance against cytotoxic T cells, among others, through upregulation of receptors, such as cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) and programmed death ligand (PD-1), that negatively regulate anti-tumor T cells (Houot et al., 2015). The development of monoclonal antibodies targeting these receptors has led to immune checkpoint therapy, which, in combination with other treatments, has been used for the treatment of melanoma, non-small cell lung cancer and renal cell carcinoma. Vaccines containing tumor-associated or tumor-specific antigens provide another method for the elimination of tumor cells. Most vaccines in cancer treatment are designed to induce cytotoxic T cell responses.

CD8 $^{+}$ cytotoxic T lymphocytes are the main weapons of the immune system against tumor cells, though the latter develop various mechanisms to escape immune recognition. The efficacy of the aforementioned therapies is usually measured by CTL assays, such as IFN γ , granzyme B and/or perforin ELISpot, flow cytometric evaluation of cell-mediated cytotoxicity and detection of CD107 surface marker of degranulation (Zaritskaya et al., 2010). Emerging single-cell techniques, including RNA sequencing and mass cytometry, supplemented by powerful computational tools for the analysis of resulting data, enable the in-depth characterization of diverse T cell subtypes and differentiation stages to: (1) illustrate potential treatment targets, (2) to monitor and assess the response to treatment, and (3) to develop new, personalized therapeutic strategies for cancer (Simoni et al., 2018; Stubbington et al., 2017).

Primary immunodeficiency

Primary immunodeficiencies (PIDs) comprise a diverse group of inherited immune disorders, characterized by atypical or recurrent infections, as well as dysregulated immune responses (Devonshire and Makhija, 2019). Defects in the number and/or function of T cells result in viral, fungal or protozoan infections during childhood that in severe cases are accompanied by failure to thrive (Albert-Vega et al., 2018). Due to the clinical and immunological diversity of these disorders, it is imperative to precisely determine the specific defects.

T cell function assays provide a valuable tool in the diagnosis of primary immunodeficiency. First, T cell immunophenotyping by flow cytometry enables the detection and enumeration of T cell subsets, such as naïve, activated, memory, Th17 and regulatory T cells (Abraham, 2011). Activation markers on the T cell surface, as well as intracellular proteins important for the function of effector T cells, can also be detected by flow cytometric analysis. Lymphocyte proliferation assays are fundamental in the

investigation of functional deficiencies in the T cell population. [^3H]-thymidine, BrdU or EdU DNA incorporation assays and CFSE dye dilution have all been used for the assessment of T cell response after stimulation with mitogens (e.g., phytohemagglutinin), commonly encountered antigens (*Candida albicans* or Tetanus toxoid) or anti-CD3 antibodies (Abraham, 2011). Cytotoxic T lymphocytes' assays identify specific defects in cell-mediated cytotoxicity. Also, further information for T cell function in PIDs is provided by TCR repertoire analysis of diversity and clonality using spectra-typing or single-cell RNA sequencing. T cell receptor excision circle (TREC) assay, which quantifies TCR gene DNA fragments produced during T cell differentiation, and identifies recently developed T cells, has been used for newborn screening of PIDs in the last decade. TRECs are absent in severe combined immunodeficiency (SCID) and other T cell lymphopenias (Chan and Puck, 2005; El-Sayed and Radwan, 2019).

Allergy and autoimmunity

Allergic responses are characterized by effector Th2 cells producing, among other cytokines, IL-4, IL-5, IL-9 and IL-13. IL-4 and IL-13 are implicated in the class switching of B cells to produce IgE, initiating the allergic cascade (Akdis and Akdis, 2015). For the assessment of immune tolerance against allergens it is essential to identify allergen-specific Foxp3⁺ CD25⁺ regulatory T cells (Tregs) and IL-10, IL-35 and TGF- β production (Kucuksezer et al., 2020). A special issue arising in the immunological study of allergy is the sparsity of allergen-specific T cells in peripheral blood that poses significant technical difficulties. To overcome this problem, functional and phenotypic analyses are often performed after an expansion step has first taken place. However, this approach is susceptible to bias, because in vitro culture after stimulation with allergen peptides may unpredictably affect the phenotypic and functional characteristics of the T cell subsets in question (Bacher and Scheffold, 2018). pMHC-multimers that specifically bind to the TCR, in combination with magnetic enrichment of all allergen-specific T cells, have been applied to avoid the inherent biases of prolonged culture methods. The disadvantages of this approach are that it can be applied only on previously known antigenic epitopes, and that it is HLA restricted. Cytokine secretion and activation-induced markers have also been used for the assessment of allergen-specific responses in short-term activation assays. The production of Th2-specific cytokines, such as IL-4, IL-5, and IL-10 from specific T cells can be assessed through cytokine secretion assays, ELISpot, ICS and RNA sequencing, whereas CD40L and 1-4BB have been used as activation-induced markers (Anderson et al., 2009; Bonvalet et al., 2011). Furthermore, T cell function assays have been essential for the assessment of the immunosuppressive capacity of allergen-specific immunotherapies in allergy treatment (Bacher and Scheffold, 2018).

Autoimmunity is caused by the inability of the immune system to discriminate between the self and the non-self. Antigen presentation to T cells and loss of self-tolerance are of great importance to this process. Auto-reactive T cells normally undergo central (thymus) or peripheral deletion and functional inactivation (anergy). Treg cells also play an important role suppressing autoimmune responses (Serra and Santamaria, 2019). Th1 and Th17 responses, as well as dysregulation of Treg function have been extensively studied for their role in the pathogenesis of various autoimmune diseases, especially in multiple sclerosis, type 1 diabetes, rheumatoid arthritis, systemic lupus erythematosus, and others (Khan and Ghazanfar, 2018; Riedhammer and Weissert, 2015). The investigation of T cell function, pathogenic phenotypes, cytokine expression and TCR repertoire analysis in relation to autoimmunity has provided a wealth of information for the pathogenesis and potential therapeutic targets of immunotherapy (Bronge et al., 2019; Jiang et al., 2020). Today, there are multiple monoclonal antibodies for the treatment of autoimmune diseases targeting and blocking the pathways leading to auto-reactivity in specific loci. T cell function assays are also important in studies investigating the efficacy of these drugs, as well as in the research for the development of new antigen-specific treatments (Serra and Santamaria, 2019).

Introduction

Phagocytosis is a fundamental activity necessary for host defenses against infection and for the clearance of apoptotic and necrotic cells (Gordon, 2016; Witko-Sarsat et al., 2000). Circulating cells, such as neutrophils, eosinophils, and monocytes, can ingest and digest particles at sites of infection and sites of injury. Tissue cells, such as macrophages, also ingest and degrade exogenous and endogenous particles in response to infection or tissue injury. Most clinical studies use circulating neutrophils to study phagocytosis, but it is also possible to recover alveolar macrophages using bronchoscopy and study these cells *in vitro*. Defects in phagocytosis can significantly increase the likelihood of serious infection, and evaluating neutrophil function becomes important in patients with recurrent deep-seated infections.

Phagocytosis requires contact at the surface of the phagocytes with the microbe or injured tissue through either specific receptors or nonspecific receptors. The initial events involve the formation of the phagosome, ingestion of the phagosome, and fusion of the phagosome with intracellular lysosomes for inactivation and digestion (Fig. 1). Other essential events involve the movement of the phagocytes to the site of injury through chemotaxis. In this review we will discuss laboratory methods needed to measure some aspects of neutrophil function with a focus on phagocytosis.

Phagocytic activity using clinical samples

Phagocytosis assays using whole blood can use viable bacteria or fungi (Wardle, 1986). These assays present practical difficulties, including maintaining bacterial stock, standardizing the number of bacteria in assays, and identifying the exact phagocyte involved in microbial killing. An alternative approach involves the use of inert beads that have different fluorescent reporters (Simons, 2010). For example, Zymosan particles are prepared from yeast cell walls and have an approximate size of 3 μm . These particles can be treated with fluorescent reporters to identify uptake into cells and can be treated with an oxidation sensitive fluorescent molecule that would identify oxidative activity in the phagocytes. Zymosan is a glucan with repeating glucose units on the surface of yeast and can be ingested by monocytes, neutrophils, and macrophages through various receptors independent of opsonization (Figs. 1 and 2).

Gupta-Wright et al. used whole blood from control subjects and HIV-tuberculosis infected patients to determine phagocytic activity; this study illustrates the use of the methods listed below (Gupta-Wright et al., 2017). These zymosan particles were coupled to a fluorochrome (Alexa Fluor 405-SE, Invitrogen) and an oxidation sensitive fluorescent reporter (OxyBURST[®] Green

Fig. 1 Phagocytic pathway. Ingestion of exogenous particles results in a dynamic sequence of complex events from plasma-membrane fusion and fission to the formation of intracellular vesicles, maturation of phagosomes, and progressive acidification and ultimately phagolysosomal fusion and digestion. The biosynthetic and secretory pathways intersect with the phagocytic pathway. Adapted from Gordon S (2016) Phagocytosis: An Immunobiologic process. *Immunity* **44**: 463–475 and used with permission.

Fig. 2 Fluorescence microscopic imaging of phagocytosis of opsonized zymosan by fluorescently-tagged porcine neutrophil. Zymosan particle is located near the neutrophil (0 s). Zymosan is engulfed by the neutrophil (30 s) and phagocytosis was completed (90 s). The fluorescent signal of hypochlorous acid generated in the phagosome was detected with a probe (240 s). Adapted from Koide Y, Urano Y, Hanaoka K, Terai T and Nagano T (2011) Development of an Si-rhodamine-based far-red to near-infrared fluorescence probe selective for hypochlorous acid and its applications for biological imaging. *Journal of the American Chemical Society* **133**: 5680–5682 and used with permission.

H2DCFDA-SE, Invitrogen). The phagocyte ingesting the zymosan particle was identified using antibodies specific for either neutrophils or monocytes. All blood samples were incubated with the zymosan particles at 37 °C, and samples were taken at 10, 30, 60, 90, and 180 min of incubation. After lysis of red cells, leukocyte suspensions were analyzed with flow cytometry to measure both uptake and oxidative burst. There was some variability among control subjects but clearly significant ingestion with an oxidative occurs in 30–60 min. Patients with HIV and active tuberculosis had reduced oxidative activity at all time points in this assay. The use of electron microscopy provides definitive proof of particle ingestion.

Methods for isolating monocytes and macrophages and measuring phagocytosis**Isolation of primary human monocytes**

1. Collect blood samples from subjects into heparinized BD Vacutainer[®] plasma tube (BD, United States), invert several times gently and proceed to monocyte isolation.
2. Fill Greiner LeucoSep tubes (50-mL) (Millipore Sigma, United States) with 15 mL Ficoll-Paque PLUS (GE Healthcare, IL, United States) and centrifuge for 30 s at $1000 \times g$ at room temperature.
3. Dilute blood sample in phosphate-buffered saline (PBS) (1:2 dilution) and distribute 30 mL of diluted blood on each LeucoSep tubes.
4. Using density gradient centrifugation at $1000 \times g$ for 10 min (without deceleration), separate peripheral blood mononuclear cells (PBMCs), collect cells from the interphase and wash 3 times with PBS at $300 \times g$ for 5 min at ambient temperature.
5. After last wash, remove the supernatant and add 10 mL ACK lysing buffer (Thermo Fisher Scientific, United States) and incubate for 10 min to lyse red blood cells.
6. Wash cells with PBS as above and resuspend in EasySep Buffer[™] (Stemcell Technologies, Canada). Count cells and adjust cell concentration to 5×10^7 cells per mL.
7. Isolate monocytes by immunomagnetic negative selection using the EasySep Human Monocyte Isolation Kit according to manufacturer's instructions and proceed to differentiation and activation of macrophages.

Differentiation and activation of macrophages

1. Culture primary human monocytes in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% heat-inactivated fetal bovine serum (FBS) + 1% Non-Essential Amino Acid (NEAA) + 100 µg/mL penicillin-streptomycin (all from Thermo Fisher Scientific, United States) with 50 ng/mL Macrophage Colony-Stimulating Factor (M-CSF) (R&D Systems, United States) in a 175 cm² cell culture flask with Nunclon Delta Surface (Thermo Fisher Scientific, United States) for 5 days.
2. On day 6, activate M0 macrophages for 24 h with either M-CSF (10 ng/mL), GM-CSF (10 ng/mL) and lipopolysaccharide (LPS) (10 ng/mL, Millipore Sigma, United States) for M(GM-CSF, LPS) macrophages; or M-CSF (10 ng/mL), IL-4 (10 ng/mL) and IL-13 (10 ng/mL) for M(IL-4, IL-13) macrophages. All cytokines are from R&D Systems.

Phagocytosis assay using flow cytometry

1. Procure *Staphylococcus aureus*, *Escherichia coli* and zymosan A particles conjugated with pHrodo red and pHrodo green from Thermo Fisher Scientific.
2. Label Aliphatic Amine Latex Beads (Thermo Fisher Scientific, United States) with pHrodo Green STP Ester or pHrodo Red Succinimidyl Ester (Thermo Fisher Scientific, United States) according to the manufacturer's instructions.
3. Add beads or particles to cells (isolated above) at indicated concentrations (manufacturer's instruction) and incubate at 37 °C for 1 h in 5% CO₂.
4. For primary human macrophages, perform phagocytosis assays in UpCell plates (Thermo Fisher Scientific, United States), which allow cells to detach without enzymatic digestion of proteins.
5. Place plates containing cells on ice to stop further phagocytosis and stain for live cells with DAPI (Thermo Fisher Scientific, United States).
6. Analyze cells on BD LSRFortessa[™] X-20 or sort on BD FACSMelody[™] Cell Sorter (BD Biosciences, United States). Representative images of phagocytosis of opsonized zymosan particle is shown in Fig. 2.
7. Gate cells based on forward scatter/side scatter properties, singlets and live (DAPI) cells using FlowJo v10.7 (FlowJo LLC, United States) and determine the frequency of pHrodo+ cells and/or the mean fluorescence intensity.

Phagocytosis assays using high-content image screening

1. Seed macrophages into poly-D-lysine-treated 96-well view plates (Perkin Elmer, United States) in DMEM 24 h before phagocytosis assay.
2. Prepare Hoechst staining solution by diluting Hoechst stock[®] solution (Thermo Fisher Scientific, United States) 1:2000 in PBS.
3. Remove the culture medium and add sufficient staining solution to cover the cells and incubate for 10 min protected from light for detection of nuclei.
4. Replace cell culture medium and add pHrodo particles suspension to the well.
5. Perform kinetic measurements using the high-content imager Opera Phenix[™] (Perkin Elmer, United States) at 37 °C and 5% CO₂ by imaging four fields from each well using the 20 × objective. Add cytochalasin D (an inhibitor of phagocytosis) in some wells as controls.
6. Perform image analysis using Columbus[™] (Perkin Elmer). Hoechst 33342-stained nuclei and the cytoplasm around each nucleus can be identified as well as the pHrodo green-positive spots within this region.
7. To calculate normalized intensities, multiply the area and fluorescence intensity of the pHrodo spots and divide by the number of nuclei per image.

Functional analysis of phagocyte activity in whole blood

1. To quantify phagocytic activity and the magnitude of the superoxide burst, use zymosan particles coupled to Alexa Fluor 405-SE (Thermo Fisher Scientific, United States) and an oxidation-sensitive fluorescent reporter (OxyBURST[®] Green H2DCFDA-SE, Thermo Fisher Scientific, United States).
2. Prepare zymosan reporter particles by washing 6 mg of zymosan (Millipore Sigma, United States) three times in PBS by centrifuging at $5000 \times g$ for 1 min.
3. Resuspend particles in 950 μ L coupling buffer (0.1 M boric acid to pH 8.0 with NaOH) containing 10 μ L of 25 mg/mL OxyBURST-SE/DMSO stock solution and 5 μ L of 5 mg/mL Alexa Fluor 405-SE/DMSO solution, mix well and incubate on a rocker in the dark for 1 h at ambient temperature and washed with 1 mL of coupling buffer.
4. Wash coupled particles three times in PBS and store in 1 mL PBS containing 0.01% sodium azide in the dark at 4 °C with a final stock concentration of approximately 5×10^6 particles/mL.
5. Wash 50 μ L of stock zymosan particle suspensions three times in 1 mL RPMI-1640 to remove sodium azide and resuspended in 250 μ L RPMI-1640 to give a 1:6 dilution (final concentration, 8×10^5 particles/mL).
6. Add 20 μ L of washed diluted particles to 1 mL of diluted whole blood (1:1 in warm RPMI-1640) and incubate at 37 °C with rocking to ensure particles and cells remain in suspension. Prepare diluted blood without zymosan reporter particles in parallel to act as control.
7. Assess phagocytosis of zymosan reporter particles and superoxide burst at predetermined time points (e.g., 10, 30, 60, 90, and 180 min) after the addition of reporter particles.
8. Harvest 100 μ L of diluted blood from the zymosan reporter and control tubes 10 min before each time point for cell surface staining. Note: phagocytosis continues during cell surface staining of live cells.
9. Stain harvested diluted blood with appropriate dilutions of antibodies for 10 min (anti-CD45 PerCP 1:33, anti-CD66b APC 1:50, and anti-CD14 PE-Cy7 1:100; all from BioLegend, United States).
10. Add 3 mL of BD FACS lysing solution containing formaldehyde and diethylene glycol to each tube and incubate for 10 min in order to stop all biological activity, lyse red blood cells and fix the white blood cells.
11. Wash cells once in PBS by centrifuging at $500 \times g$ for 10 min, add CountBright[™] counting beads (Thermo Fisher Scientific, United States) according to manufacturer's instruction and acquire on a CyAn ADP flow cytometer (Beckman Coulter, United States).
12. Analyze data using the FlowJo version v10.7 (FlowJo LLC, United States).

Intracellular oxidative activity

The generation of reactive oxygen species during the phagocyte respiratory burst is initiated by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, a membrane-bound enzyme complex found in the plasma membrane and phagosomes. This complex functions to catalyze the transfer of an electron from NADPH to O_2 , producing superoxide (O_2^-) after interaction with inflammatory stimuli (Gordon, 2016; Witko-Sarsat et al., 2000). Superoxide functions as a precursor to other reactive oxygen species, such as hydrogen peroxide, hypochlorous acid, and hydroxyl radical. Superoxide dismutase catalyzes the generation of hydrogen peroxide, which may then form hydroxyl radicals by either the Haber-Weiss reaction or Fenton reaction. In addition, myeloperoxidase can catalyze the production of hypochlorous acid from chloride ions and hydrogen peroxide.

Oxidative activity can be measured using either the nitro-blue tetrazolium test or the dihydrorhodamine test. For example, patients with chronic granulomatous disease of childhood that do not have oxidative bursts have no black deposits with the nitro-blue tetrazolium test (Häger et al., 2010; Campos et al., 1974; Freeman and King, 1972). The dihydrorhodamine test measures nicotinamide alanine dye nucleotide phosphate oxidase activity (Henderson and Chappell, 1993; Koide et al., 2011). A nonfluorescent dye is taken up by the neutrophils and becomes fluorescent after reaction with reactive oxygen species produced by the respiratory burst. Neutrophils from a patient with X-linked chronic granulomatous disease of childhood do not fluoresce after stimulation (Fig. 3) (Dimitrova et al., 2013). Both these assays can be modified to include endotoxin stimulation or phorbol myristate acetate stimulation of the patient's neutrophils. The nitro-blue tetrazolium assay can be modified to give quantitative measurements of the oxidative burst (Choi et al., 2006).

Methods to measure intracellular oxidative activity

Nitro-blue tetrazolium assay

1. The nitro-blue tetrazolium test requires a small amount of anticoagulated blood. 0.1 mL of blood is mixed with 0.1 mL of 0.2% nitro-blue tetrazolium in saline and 0.1 mL of phosphate buffered saline. This mixture is incubated at 37 °C for 15 min and then held at room temperature for 15 min.
2. Smears are made on a glass slide and fixed with methanol for 3 min and then stained with Pappenheim's stain for 3–5 min. Neutrophils that ingest the dye and have an oxidative burst create large black formazan deposits in the cytoplasm (Fig. 3).
3. This assay should be run in conjunction with blood from healthy control subjects to identify problems with specimen handling.

Fig. 3 Nitro-blue tetrazolium blue formazan staining of neutrophils (top left panel) and the blue to purple black precipitate in the zymosan stimulated neutrophils (top right panel) in a normal patient. Reduced or no formazan staining of neutrophils (bottom left panel) and no blue/black deposit staining in zymosan stimulated neutrophils (bottom right panel) in patients with chronic granulomatous disease. Adapted from Dimitrova G, Bunkall C, Lim D and Kendrick C (2013) Comparison of two methods for the diagnosis of chronic granulomatous disease—Neutrophil oxidative burst measured by the nitroblue tetrazolium slide test versus the dihydrorhodamine 123 flow cytometric assay. *New Zealand Journal of Medical Laboratory Science* **67**(2): 45–51 and used with permission.

Dihydrorhodamine test

1. Incubate heparinized blood at 37 °C in the presence of dihydrorhodamine 123. Add phorbol myristate acetate (PMA) or formyl-methionyl-leucyl-phenylalanine (fMLP) stimulant mix with the whole blood specimen for additional incubation at 37 °C.
2. Centrifuge the specimen and lyse the cell pellet with ammonium chloride at ambient temperature.
3. Wash with azide-free phosphate buffered saline (PBS) and stain with a viability marker and CD15 (a marker for myeloid cells) at ambient temperature.
4. Wash the cells, centrifuge, and resuspend in 1% paraformaldehyde. Identify viable neutrophils with a viability dye and confirm by the presence of CD15.
5. Determine the percent DHR positive cells and calculate the delta % DHR-positive neutrophils after PMA or fMLP stimulation and mean fluorescence intensity (MFI) for each stimulant using DHR flow cytometry.

Neutrophil granules

Neutrophils have three granule types that can be identified using routine stains and by measuring enzymatic activity in particular granules (Häger et al., 2010). The primary or azurophilic granules contain elastase and myeloperoxidase. The secondary or specific granules also contain multiple enzymes, including lactoferrin (Fig. 4). The tertiary granules contain gelatinase. These granules subsets have varying sizes and varying intensity when stained with 3, 3' diaminobenzidine, peroxidase reactive dye. Myeloperoxidase is present in the primary azurophilic granules of neutrophils and monocytes; it catalyzes the production of HOCL from chloride and hydrogen peroxide. Complete myeloperoxidase deficiency occurs in approximately 1 in 4000 individuals. This deficiency can be identified in laboratory tests by staining neutrophils and monocytes with a peroxidase (Fig. 4).

Chediak-Higashi syndrome is a rare, autosomal recessive disorder that is characterized by oculocutaneous albinism, progressive neurologic abnormalities, coagulation defects and recurrent bacterial infections (Häger et al., 2010). Due to a mutation in the

Fig. 4 Electron micrograph of neutrophil. The presence of multilobed nucleus is apparent and the primary, azurophilic granules are larger and rounder than the secondary, specific granules. (http://medcell.med.yale.edu/histology/blood_bone_marrow_lab/neutrophil_em.php).

CHS1/LYST gene, cells are defective in organelle trafficking, fusion, and transport. Often, lysosomes will fuse with one another as opposed to phagosomes resulting in large cytoplasmic granules. Individuals with this disorder develop recurrent, severe infections, most commonly in the skin, respiratory tract, and mucous membranes. Evaluation for this disease is often prompted in individuals with recurrent bacterial infections or other signs and symptoms, such as oculocutaneous albinism and recurrent bleeding events. Diagnosis is made based on visualization of peroxidase positive lysosomal granules in peripheral blood granulocytes.

Methods to analyze neutrophil granules

Neutrophil identification in peripheral smears

1. The name neutrophil derives from staining characteristics on hematoxylin and eosin (H&E) histological or cytological preparations. Basophilic white blood cells stain dark blue, eosinophilic white blood cells stain bright red, neutrophils stain a neutral pink.

Neutrophil isolation using centrifuge gradients

1. Bring all reagents to room temperature
2. Collect 5.0 mL of neutrophil isolation media in centrifuge tube. Carefully layer 5.0 mL of blood over the separation media. Perform this step slowly and carefully, and with the pipette tip close to the surface of the media to avoid mixing the blood and the media.
3. Centrifuge at 500 g for 35 min at 20–25 °C. The blood should separate out into six distinct bands: plasma, monocytes, isolation media, neutrophils, more isolation media, and the red blood cell pellet. If these bands are not clear, the separation process was not clean and will need to be repeated.
4. Carefully remove the top three layers (plasma, monocytes, and isolation media) using a pipette. Dispose of these layers.
5. Carefully pipette the layer of neutrophils and all of the isolation media beneath the neutrophils. Place the solution into a clean centrifuge tube.
6. Dilute the neutrophil solution to 10 mL with HBSS without $\text{Ca}^{2+}/\text{Mg}^{2+}$. Invert the tube a few times to suspend the cells.
7. Centrifuge the neutrophil solution at 350 g for 10 min. A red pellet should be present at the bottom of the tube, containing neutrophils and residual red blood cells (RBCs). Remove the supernatant with a pipette carefully so that the pellet is not disturbed.
8. Lyse the residual RBCs by adding 2 mL Red Cell Lysis Buffer to the tube. Resuspend the pellet by vortex the vial at a setting of 3–4. Avoid increasing the vortex setting above 4, since this may cause the neutrophils to activate. If necessary vortex for several seconds, or “pulse” the vortex to dissolve the pellet.
9. Centrifuge the tube at 250 g for 5 min. Remove the supernatant with pipette. Repeat the lysing process if required.
10. Add 500 μL HBSS without $\text{Ca}^{2+}/\text{Mg}^{2+}$ to each tube. Again, vortex to resuspend the pellet at a setting of 3–4. Dilute to 10 mL with HBSS without $\text{Ca}^{2+}/\text{Mg}^{2+}$.
11. Centrifuge the tubes at 250 g for 5 min. Aspirate the supernatant and discard.
12. Resuspend the pellet in 250 μL HBSS/HSA Solution (2% HSA). Cells may then be counted and adjusted to desired concentration.

Stains for granules and granular enzymes

1. Fix air-dried blood smears with ethanol.
2. Add benzidine or 3,3'-diaminobenzidine or p-phenylenediamine dihydrochloride to a buffer solution.
3. Incubate the slide for 10 min, washed with tap water, and then counter stained with hematoxylin for 3–5 min.
4. Identify myeloperoxidase activity using microscopy in the primary granules of neutrophils and eosinophils. <http://laboratorytests.org/myeloperoxidase-mpo-stain/>.

Chemotaxis

Neutrophil responses to infection injury require directed migration to the relevant site. This activity requires neutrophil attachment to endothelial surfaces, diapedesis through the endothelium, and then movement to the site of injury. This chemotactic process can be measured in the laboratory. Patients with reduced chemotactic activities have impaired host defense responses.

Methods to measure chemotaxis

1. Measuring neutrophil chemotaxis is a technically complex and is usually done in very specialized laboratories. An alternative approach is to measure CD11b levels on stimulated neutrophils using flow cytometry (Nicholson et al., 2007). Patients with leukocyte adhesion deficiency type I have deficiencies of beta-integrins in neutrophils. This deficiency causes abnormalities in adherence, chemotaxis, C3bi mediated phagocytosis, degranulation, and respiratory burst. These patients have persistent granulocytosis. They have recurrent infections without neutrophil infiltration, and consequently there is limited formation of pus at sites of infection. CD11b is present in secondary and tertiary granules of neutrophils. Monoclonal antibodies can determine its presence or absence in resting and stimulated neutrophils.
2. A second approach involves the use of microfluidic chambers to measure chemotactic responses. Yang have provided a detailed outline of the procedures involved in these studies (Yang et al., 2017a,b).
3. This section does not include methods in detail. Please see references.

Summary

Questions about neutrophil function often arise in patients with recurrent deep-seated infections. The initial evaluation of these patients should include neutrophil counts and blood smears to analyze neutrophil morphology. Relatively simple laboratory tests can determine whether or not neutrophils have normal oxidative activity using the nitro-blue tetrazolium test and whether or not neutrophils have normal granules with myeloperoxidase activity. Measuring phagocytosis and chemotaxis involves more specialized laboratory techniques and typically requires testing by referral laboratories.

Glossary

Multiplicity of infection (MOI) The number of microorganisms per cell included in the in vitro infection assay. If the number of microorganisms to PMN the same, then the MOI is one, whereas if the number of microorganism to PMN is 10 times higher, then the MOI is 10.

Nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase/Nox2 oxidase (NOX2) A membrane-bound enzyme complex that faces the extracellular space, being found in the plasma membrane as well as in the membranes of phagosomes of neutrophils. It catalyzes the production of a superoxide free radical by transferring one electron to oxygen from NADPH.

Trained immunity Is the modification of cells of the innate immune system that derives in immunological memory.

Introduction

Neutrophils, also known as polymorphonuclear neutrophils (PMNs) are a type of granulocytes and the most abundant type of leukocytes, comprising approximately 60% of the nucleated cells in blood and bone marrow. PMNs are the first line of defense against pathogens being the first immune cells that arrive at the infection site in response to chemotactic factors produced by host-microbe interactions. Typically it has been accepted that a mature PMN has a circulating half-life that ranges from 6 to 8 h in blood and then survives in tissues around 2–3 days. As a consequence, their role has historically been linked to the initial phases of defense being considered as short-lived, non-specialized cells. However, recent research has redefined them as efficient and versatile effector cells (Tecchio and Cassatella, 2016; Warren et al., 2017) that possess functional heterogeneity and plasticity being able to shape adaptive immune responses (Leliefeld et al., 2015) and showing functions that link innate and adaptive immune responses (Tillack et al., 2012). PMNs have recently shown to be an important part of trained immunity showing that they can go thorough transcriptomic and epigenetic rewiring that makes them anti-tumoral when treated with β -glucan (Kalafati et al., 2020) or inducing enhanced antimicrobial functions after BCG vaccination (Simone JCFM Moorlag et al., 2020).

PMNS are crucial for host health maintenance. Inherent deficiencies in PMN microbiocidal activity or even an overall reduction in PMN abundance (neutropenia) is detrimental to health leading to more severe and frequent infection susceptibility. In response to inflammatory stimuli, PMNs migrate from the blood circulation to infected tissues, where they kill microbes through a set of

Fig. 1 Mechanisms used by PMNs to combat pathogens: phagocytosis, degranulation, reactive oxygen species production and release of extracellular traps.

immune mechanisms that include phagocytosis (Mayadas et al., 2014), reactive oxygen species (ROS) production (Mayadas et al., 2014), exocytosis of lytic enzymes with potent antimicrobial activity known as degranulation (Jimbo et al., 2017; Mayadas et al., 2014) and the release of extracellular traps (ETs) (Brinkmann et al., 2004; Cassatella et al., 2009) (Fig. 1).

During the last three decades, research involving PMNs and their roles in health and disease has suffered a huge burst. In this paper we intend to describe the mechanisms and the methodology that will enable measuring these major functions of PMNs in response to infectious agents.

PMN isolation

Some functional assays can be performed both directly on whole blood or bone marrow or if desired on isolated PMNs, whereas other assays need purely isolated PMNs. Purity should be over 90% in order to distinguish the effects of PMNs from those of other leukocytes in the sample and also to avoid undesired effects derived from the interaction with other leukocytes in the sample. Since PMNs cannot tolerate the freezing-thawing process they should not be isolated and stored in liquid nitrogen for posterior analysis but tested fresh after isolation. Evaluating functional activity on purified PMNs is, therefore, time-consuming because isolation must be performed at each testing.

Efforts have been made by different groups to overcome this issue and different storing conditions of whole blood have been tested with the aim of providing a larger time frame to cover sampling and posterior testing. Lizcano et al. (2017) have compared PMNs maintained in whole blood for various periods at different temperatures with freshly purified PMNs, testing for viability, a very necessary characteristic to enable performing functional tests. In their study, PMNs that had been maintained in whole blood at 4 °C for up to 24 h had a longer lifespan compared to purified PMNs maintained in the same conditions (Lizcano et al., 2017). These findings suggesting that blood whole can be stored with minimum PMN viability loss are very helpful and promising. Another study, has tested freeze-thawing conditions, showing that whole blood cryopreservation can be performed for immunophenotyping of most blood cells and for ex vivo functional analyses of T cells, as expected, but reporting loss of PMNs (Braudeau et al., 2021). This data indicates that improvements on cryopreservation for PMNs need further research and of course PMN functionality after storage needs testing, as well. In this context, the recommendation is to test freshly isolated PMNs for reliable results and only then, go to further storing or treatment condition comparisons.

Either for whole blood and bone marrow or pure PMN assays, different anticoagulants have been tested (EDTA, heparin and citrate) and even the needle has been suggested as an influencing parameter when drawing the blood sample because shear forces have been thought to damage and/or activate PMNs. There have been discrepancies on which anticoagulant is best and while some authors have shown that assay results can be influenced by the anticoagulant (Freitas et al., 2008), another recent study (Krabbe et al., 2020) has reported that the blood collection technique and anticoagulants have minor effects on the isolation of PMNs.

Storing isolated PMNs at 37 °C for over 1 h does have an effect on final PMN count and ROS activity as shown by Krabbe et al. (2020). These findings suggest that functional assays with isolated PMNs should be carried out as rapid as possible to preserve functionality. PMNs are considered fragile cells that are easily activated and damaged if not properly handled. Maintaining PMNs in as similar as possible to basal in vivo conditions is therefore, essential both during and after isolation. Although isolated PMNs should be well mixed to achieve a homogenous suspension, effort should be made to not perform vigorous mixing. The chemistry and temperature of the buffers used along the process must be carefully managed. Buffer composition will depend on the animal species and the mechanism object of the study since the addition of media supplements can strongly influence the outcome of experiments. As an example, serum-free media is encouraged to study extracellular trap release in murine PMNs, whereas for human PMNs media can contain serum (Neubert et al., 2019). In addition, PMN suspension in PBS supplemented with glucose to avoid cell clumping is highly recommended until the functional assays are performed (Kuhns et al., 2015).

There are many different isolation methods but they all share some steps: dextran sedimentation, density gradient separation and red blood cell (RBC) lysis step. Dextran sedimentation does not work well for all species although, the PMN yield from blood of some species, such as human and rabbits (Kouh et al., 2000) can benefit from this first step. Dextran promotes RBC aggregation and sedimentation, leading to the formation of a rich leukocyte plasma layer above the RBC sediment, ultimately removing most of the erythrocytes. Basically, the incorporation of this step prior to density gradient separation minimizes the number of RBC lysis steps that must be performed at the end of the isolation protocol. The density gradient step is directed at achieving the separation of PMNs from less-dense monocytes and lymphocytes. The density media and composition varies widely between species due to slight differences in PMN density. In the final, hypotonic lysis step residual RBCs are eliminated. Lysis protocol should also be adapted to the target species since there are also differences in RBC reactivity, susceptibility to lysis and different levels of aggregation and binding of the RBCs to the PMNs between species. In addition, PMNs can be damaged with the lysis protocol directed at RBC, affecting their viability and activation status. Therefore not all lysis methods are valid for PMNs of all species and this should be checked.

Human PMNs isolation protocols are much more standardized compared to non-human species PMN isolation. However, as mentioned before the great research explosion on PMNs in all animal species has made many different protocols accessible. There are easy to follow protocols for human (Kremserova and Nauseef, 2020; Siemsen et al., 2020) and non-human species such as mice (Pulavendran et al., 2020; Siemsen et al., 2014), rat (Caldefie-Ch  zet et al., 2002), rabbits (Siemsen et al., 2020) or even large animals such as bovine (Ladero-Au  n et al., 2021; Rambault et al., 2021; Siemsen et al., 2020), ovine (Arteche-Villasol et al., 2020; Siemsen et al., 2014) and goat (Arteche-Villasol et al., 2020; Patel et al., 2020). The election of the isolation method will therefore depend on the animal species target of the study, the available sources and also the functional assay that it is intended for. Assaying more than one method before deciding in order to establish optimum conditions for each laboratory is highly recommended.

In addition to these traditional isolation protocols, immunomagnetic enrichment is possible for some species. PMN purification can be achieved by negative immunoselection with magnetic beads in mice (Hasenberg et al., 2011) and humans (Pelletier et al., 2010). This technology can yield PMN purity upto 99% and is appropriate for performing transcriptomic studies for which RNA contamination from other cell types is undesirable.

Phagocytosis

Phagocytosis is the process through which various types of cells engulf particulate matter. The origin of the word phagocyte is greek, from *phago* meaning eating or devouring and the suffix *cyte* which stands for cell. It was   lie Metchnikoff who coined this term when developing the theory of phagocytosis back in 1884. At that time, he named cells from the bloodstream with phagocytic activity as *macrophages* and *microphages*, the latter is what we know today as PMNs. PMNs are the major phagocyte subset in the bloodstream. PMNs are professional phagocytes, just as macrophages and dendritic cells, meaning that they possess receptors on their surface that permit recognition of pathogens for their ingestion into phagosomes, which fuse with lysosomes afterwards enabling the digestion of the microorganism (Gordon, 2016). Indeed, phagocytosis can be aided by complement and/or antibody receptors that are present on the cell surface (Lee et al., 2003), but can also occur in absence of these opsonins. After ingestion and once inside the PMN, pathogens are exposed to ROS and antimicrobial peptides, components, which kill and lyse most of the microorganisms (Nordenfelt and Tapper, 2011), although some pathogens have developed evasion mechanisms to inhibit the killing action of phagocytosis (Kobayashi et al., 2018).

Basically, in a phagocytosis assay, phagocytes are incubated with pathogens or particles that can be labelled or not. Fluorescently labelled pathogens and particles greatly aid analysis. These can be FITC-stained (Hussen et al., 2016), or pHrodo-stained (Lindner et al., 2020) or pathogens carrying plasmids that express fluorescent proteins like GFP, YFP, etc. (Hellebrekers et al., 2017) can be used, as well. The proportion of particles or pathogens to PMNs put into the assay, also named multiplicity of infection (MOI) should be determined for each type of target. In most cases, pathogens or particles should be opsonized before ingestion by PMNs. This opsonization step must be performed before incubation with PMNs so that it does not limit the process. When studying the implication of receptors, inhibitors can be added previous to the contact with the particles or pathogens. Afterwards, carrying out the phagocytosis assay with shaking, aids continuous contact between PMNs and targets. Normally phagocytosis will be performed at 37   C, so including a PMN-pathogen suspension in ice (4   C) will permit having a negative control (absence of phagocytosis and only binding of the targets to the surface). This is essential if flow cytometry is to be performed as it is not possible to distinguish from PMNs with ingested particles or PMNs with only bound particles to the surface.

After incubation, the ingestion of the particles or their loss from the media can be measured by microscopy and flow cytometry. Microscopy permits obtaining images that will support the results obtained by the automatized methods. Furthermore, the micrographs can be analyzed with image software. Flow cytometry is advantageous as it permits the analysis of a high number of cells, providing results in a short period of time with a small volume of sample.

Phagocytosis by fluorescent microscopy

Samples can be taken at different time points and the phagocytic index may be determined by counting the number of internalized fluorescent targets divided by the total number of cells counted. Also, the phagocytic efficiency index can be determined by counting the number of PMNs with at least one internalized fluorescent target, divided by the total number of cells counted. This can be done manually or combined with the Cell Counter plugin on the Image J software package. Automatic particle counting can be done using the Analyze particle plugin, after setting a threshold on images and making them binary.

Phagocytosis by flow cytometry

As in microscopy, samples can be taken at different time points or at a fixed time point and phagocytosis can be measured by flow cytometry using fluorescent particles. Attention must be paid to the washing steps after incubation to ensure minimum extracellular bacteria. For this method, the number of intracellular fluorescent particles cannot be counted meaning that each PMN can contain more than one particle. The percentage of PMN ingesting particles is the measured parameter, this is, the phagocytic efficiency index. A viability dye can be added, such as Hoechst 33258 so that phagocytosis activity can be defined as the percentage of fluorescing cells among viable cells as seen on the example in Fig. 2.

Detection of reactive oxygen species ex vivo

ROS production, also named respiratory oxidative burst, is a powerful mechanism to combat microbes, being a primary component of the innate immune system against bacteria and fungi (Van Acker and Coenye, 2017). Phagocytes, such as PMNs and monocytes can produce ROS through the multi-protein membrane-bound NOX2 complex (Dupré-Crochet et al., 2013), which catalyzes the reduction of molecular oxygen to superoxide anion, which is afterwards converted to hydrogen peroxide by the action of superoxide dismutase or without the participation of this enzyme.

ROS released into the extracellular media in an uncontrolled manner can damage the host tissue being implicated in several inflammatory diseases, whereas ROS generated in the intracellular space after phagocytosis of pathogens is not toxic for the cell environment and contributes to the elimination of the pathogens (Briheim et al., 1989). These differences can be crucial when studying a particular disease. Discriminating between the intracellular and extracellular production of ROS can be done depending on the technique (Caldefie-Chézet et al., 2002). Cytochrome C reduction performed by spectrophotometry is a measure of ROS formation in the extracellular space (Kuhns et al., 2015), whereas dihydrorhodamine (DHR) reduction (Hussen et al., 2016) assessed by flow cytometry is indicative of intracellular ROS production. Both assays are based on red-ox reactions and require stimulation with a factors such as phorbol myristate (PMA) or other desired stimulants such as pathogen proteins or extracts. An alternative to these methods, is the use of chemoluminescence for which different probes can be used, such as luminol for intracellular ROS quantification and lucigenin for extracellular quantification (Caldefie-Chézet et al., 2002).

Fig. 2 Phagocytosis of *Mycobacterium avium* subsp. *paratuberculosis* (MAP)-GFP by PMNs isolated from rabbits vaccinated against mycobacteria. (A) FSC/SSC plot of isolated PMNs put in contact with Map-GFP showing gating of leukocytes, (B) FSC/SSC gating of PMNs, (C) gating of singlets, (D) histogram of showing gating of live-dead staining with Hoechst 33,258, (E) histogram showing proportion of live PMNs with ingested Map-GFP, (F) FSC/FITC plot showing proportion of live PMNs with ingested Map-GFP.

ROS determined cytochrome *c* by spectrophotometry

The assay based on the reduction of cytochrome *c*, requires isolated PMNs and it can be run over time (kinetic) involving larger volumes of purified cells or at a fixed time (static) with small volumes in 96 well plates (Kuhns et al., 2015). In the kinetic format, relatively large amounts of blood are needed, although it allows monitoring of the production of superoxide anions over time. When the experiment that is run includes a large number of samples, or when other functional assays are run at the same time and the number of available PMNs is therefore limiting, the static assay is a good option, as it can be read in an ELISA plate reader at a specific time point ranging 10–30 min. In both cases, PMNs and cytochrome *c* are mixed and allowed to equilibrate. Afterwards, a stimulus is added and the superoxide that is produced as a function of ferricytochrome reduction can be measured on a spectrophotometer. In order to correct for other reductants, controls including superoxide dismutase and non-stimulated PMNs should be included.

ROS determined with DHR by flow cytometry

The DHR assay is based on the principle that internalization of non-fluorescent DHR (reduced form) by phagocytes and posterior stimulation with PMA (Elbim and Lizard, 2009) or other stimulating factors activates the respiratory oxidative burst generating hydrogen peroxide, that oxidizes DHR to rhodamine 123, a green fluorescent compound, which can be detected by flow cytometry. ROS generation can then be calculated as the Mean Fluorescence Intensity (MFI) of gated region after subtracting the MFI of non-stimulated cells or the percentage of ROS generating cells compared to non-ROS generating of the same cell type. The assay can be performed on whole blood or on previously isolated PMNs in various types of cell culture media. Because the assay reagents are not species-specific, this assay can be used in any species or cell type capable of producing a NOX2-dependent respiratory burst response, meaning that if whole blood is used, forward scatter (FSC)/side scatter (SSC) gating can be performed to identify both monocytes and PMNs and therefore ROS activity of both phagocytes can be determined in the same sample. Added to this, flow cytometry based assays have the advantage that thousands of cells can be analyzed in a very short period of time employing small volumes of isolated PMN or even whole blood (Elbim and Lizard, 2009).

In the example shown on Fig. 3, the increase in the ROS producing population of PMNs after contact with a mycobacterial sonicate (SM) in the vaccinated animals compared to non-vaccinated animals shows a priming effect on PMNs due to vaccination against mycobacteria.

ROS determined by chemiluminescence

In this case, PMNs are plated and thermostated to 37 °C and luminol or lucigenin are added to the wells. The basal value of the chemiluminescence is measured on a luminometer. Afterwards, stimulus such as PMA (Billert et al., 2021; Caldefie-Chézet et al., 2002), zymosan (Billert et al., 2021) or fMLP (Billert et al., 2021), are added to the wells, always setting a non-stimulated cell control. Plates are incubated at 37 °C for 30–60 min afterwards, chemiluminescence is measured.

ROS production and phagocytosis in one assay by flow cytometry

In order to maximize sample use, both ROS and phagocytosis can be measured in the sample of whole blood using flow cytometry. Gupta-Wright et al. (2017) have developed a whole blood phagocyte functional assay that utilizes the inflammatory inducer zymosan, coupled to OxyBURST-SE, a fluorescent reporter of phagosomal oxidase activity. This way, both phagocytic uptake and the superoxide burst in the phagocyte populations (PMNs and monocytes) can be estimated. In the assay, whole blood is incubated with the zymosan reporter particles at 37 °C with shaking to ensure phagocyte to particle contact. Samples can be taken out to evaluate both functions at different time points. These should be collected 10 min prior to each time point to enable cell surface staining (CD45: leukocytes, CD14: monocytes and CD66b: PMNs) since phagocytosis continues during the staining process. Afterwards, RBC lysis should be performed and samples can be acquired. Finally, FSC/SSC and specific fluorescence detectors will permit gating to identify monocytes and PMNs and the shifts in populations due to the studied functions.

Antimicrobial killing assay

Many published studies report phagocytosis and ROS production and relate these parameters to killing. Although ROS can be indicative of the killing capability of PMNs, this mechanism is not exclusively related to the killing of microorganisms (Auding et al., 2003). Indeed, the killing function of PMNs is the major mechanism of PMN activity contributing to pathogen clearance and therefore proper assays measuring antimicrobial killing are very valuable.

The method described here on, involves purified PMNs since quantifying the pathogen clearance or killing ability of PMNs is the issue. In order to test for killing, the same considerations as for phagocytosis should be taken, this is, considering opsonizing the pathogen or not and also setting the appropriate MOI for the pathogen target of the assay.

Here again, PMNs are put in contact with pathogens at 37 °C for various timepoints depending on the pathogen and its growth rate. PMNs will ingest the pathogens and then extracellular non-ingested bacteria can be removed by differential centrifugation. Afterwards, colony counting can be performed after plating the pellet of PMN containing ingested pathogens and the supernatant

Fig. 3 ROS production by PMNs from whole blood with DHR from rabbits non-vaccinated and vaccinated against mycobacteria. Blood is stimulated with PBS, PMA or SM (mycobacteria sonicate) for 45 min. (A) FSC/SSC gating of non-stimulated PMNs from a non-vaccinated animal, (B) ROS producing of non-stimulated PMNs from a non-vaccinated animal, (C) FSC/SSC gating of non-stimulated PMNs from a vaccinated animal, (D) ROS producing of non-stimulated PMNs from a vaccinated animal, (E) FSC/SSC gating of PMA-stimulated PMNs from a non-vaccinated animal, (F) ROS producing of PMA-stimulated PMNs from a non-vaccinated animal, (G) FSC/SSC gating of PMA-stimulated PMNs from a vaccinated animal, (H) ROS producing of PMA-stimulated PMNs from a vaccinated animal, (I) FSC/SSC gating of SM-stimulated PMNs from a non-vaccinated animal, (J) ROS producing of SM-stimulated PMNs from a non-vaccinated animal, (K) FSC/SSC gating of SM-stimulated PMNs from a vaccinated animal and (L) ROS producing of SM-stimulated PMNs from a vaccinated animal. The increase in ROS production after contact with SM shows a priming effect on PMNs due to vaccination (comparing J and L). Data representative of $n = 5$ for each group.

containing the extracellular bacteria. Once the amount of viable bacteria is known, the killing can be determined. In this type of assay, PMNs are not separated from uningested bacteria, and so this would be a combination measure of the ability of the PMN to phagocytose and kill.

In Fig. 4 the workflow for working with mycobacteria is outlined. Mycobacteria are slow growing microorganisms and in this case a 24 h incubation to evaluate bacterial killing is appropriate (Ladero-Auñón et al., 2021). Briefly, PMNs and mycobacteria are incubated together at 37 °C 5% CO₂ for 24 h. An initial 4 °C control to establish starting CFUs should be included and also an only mycobacteria control incubated along with the samples of study to address bacterial division overtime. Afterwards, differential centrifugation should be performed, this is, a slow centrifugation step should be performed in order to pellet PMNs and supernatant containing extracellular bacteria should be separated. Finally, the pellet can be washed and centrifuged again pooling both supernatants that will contain all the extracellular bacteria. Then PMN lysis should be performed carefully not to promote DNA release as it might clump the bacteria. Afterwards serial dilutions should be performed in order to get 100 colonies per plate. Culturing in duplicate or triplicate, and more than one dilution specially for the first time when the expected killing rate is unknown.

This scheme can be adapted and optimized to other microorganisms. For example, fast growing bacteria such as *Staphylococcus aureus* require much shorter incubations, observing detectable killing as soon as 10–20 min after incubation (Magon et al., 2020). Including or not an opsonization step when preparing bacteria should be considered depending on the pathogen under study, as greater killing effects of human PMNs against *S. aureus* have been observed in non-opsonizing conditions after 60 min (Lu et al., 2014).

Fig. 4 Bactericidal assay workflow followed to evaluate mycobacterial killing by PMNs.

Another consideration is that PMNs can be heterogenous and when performing these assays on plates, differences in the killing rates between PMNs in suspension and adherent PMNs can be observed as seen by [Lu et al. \(2014\)](#). In such case, incubation times and lysis conditions should be revised. Another factor to bear in mind is that the extracellular viability loss due to cytotoxic factors secreted by PMNs cannot really be quantified by this technique.

This method does not require expensive and specialized equipment but it is time consuming due to the manual input in serial dilutions, plating and counting. However, even if colony forming units do not exactly represent a permanent loss of cell viability it is the best assessment of PMN bactericidal activity.

Degranulation and release of lytic enzymes

Degranulation and release of lytic enzymes and bactericidal peptides are considered oxygen-independent mechanisms. Degranulation or exocytosis, of membrane-bound secretory granules, is the process through which PMNs release several granule-derived mediators, such as neutrophil elastase (NE), myeloperoxidase (MPO), cathepsin G, and proteinase-3, among others into the phagosome or in the extracellular space.

While expression or protein level measurements can provide information regarding the abundance of these particular proteins, degranulation can be assessed by measuring the release or activity of these. For this reason, the method described here on, focuses on measuring the activity of MPO.

MPO activity

MPO is a lysosomal peroxidase enzyme stored in the azurophilic granules of PMNs. MPO participates in the respiratory burst producing hypochlorous acid from hydrogen peroxide and chloride anion. There are many assays to assess MPO activity and method described here involves purified PMNs treated with ortho-dianisidine dihydrochloride (Bedouhène et al., 2020).

PMNs can be briefly treated with cytochalasin B and then with pathogens target of the study and fMLF for different time periods. Afterwards, PMNs are centrifuged and MPO is measured in the supernatant after treatment with ortho-dianisidine dihydrochloride first and hydrogen peroxide after. Then solution should be mixed and read on a spectrophotometer for 10 min.

However, some authors suggest that standardization is needed to permit verification between studies (Pulli et al., 2013), pointing out the problem with lack of specificity to MPO of the most used probes (e.g., TMB, *o*-dianisidine, guaiacol). For this reason, Pulli et al. (2013) developed a highly specific and sensitive assay protocol that includes a step capturing MPO by ELISA.

Neutrophil extracellular trap (NET) release

NET release has been reported as an important novel effector mechanism against pathogens in PMNs (Brinkmann et al., 2004). NETs are extracellular structures mainly composed of chromatin and granule proteins that can trap and kill microorganisms (Fuchs et al., 2007). The formation of these structures can be triggered by some pathogens (dead and alive), danger associated molecular patterns, exogenous compounds, platelets, antibodies and inflammatory cytokines such as IL-8 and TNF (Shrestha et al., 2020; Skendros et al., 2018). Although NETs were originally reported as novel immune defense mechanism to trap and kill microorganisms, it has been accepted that the role of NETs exceeds these findings. Dysregulation of NET release or clearance has been implicated in a great number of chronic inflammatory diseases (Lood et al., 2016) and cancer (Albregues et al., 2018). Actually, NETs can have a controversial effect on tumors, being pro-tumor or anti-tumor depending on the circumstances (Liu and Liu, 2019). In this sense, NETosis can be considered a potential therapeutic target and therefore understanding PMN activity and the contribution of this cell type to each clinical setting can be important.

Although, NETs can be identified in tissues post-mortem or in biopsies and *in vivo* in animal models, the best and sometimes only way to study NET production includes the isolation of PMNs from patients, healthy donors, or animals followed by an *ex vivo* stimulation of these cells to assess and quantify NET formation. Indeed, this can be considered the gold standard of NET-experiments (Neubert et al., 2019).

ET release must be studied on purified PMNs in contact with ET inducers, mainly PMA, zymosan (Ladero-Auñon et al., 2021), interleukin-8, lipopolysaccharide and/or the pathogens under study, dead or alive (Ladero-Auñon et al., 2021). Different ET release assays have been reported and they mainly involve an automatized measurement of the extruded DNA (von Köckritz-Blickwede et al., 2010; Ladero-Auñon et al., 2021) or a visualization of the structures under the fluorescence microscope (von Köckritz-Blickwede et al., 2010; Ladero-Auñon et al., 2021). The automatized method is advantageous as it permits obtaining results in a short period of time, whereas the microscopic method permits visualization aiding interpretation and supporting the automatized method, but it is tedious if real quantification of ET release is desired.

Fluorimetry

After proper incubation of PMNs with chemotactic factors, mitogens or pathogens, ETs generated by cells are generally digested with nuclease to liberate them into the supernatant and then this activity is stopped. DNA extraction is performed on an equivalent number of PMNs in a control well in order to have an estimate a real DNA content. Thereafter, culture supernatants and the DNA control are collected and both ETs and genomic DNA are quantified using DNA fluorescent intercalating molecules. Afterwards, fluorescence quantification in an automatic plate reader can be performed and the percentage of DNA released as ET-DNA (ETosis) can be calculated by dividing the amount of quantified ET-DNA by the total amount of genomic DNA.

Visualization and quantification by microscopy

ET release for microscopy can be performed using poly-L-lysine treated coverslips or microscopy chamber slides. For either option, PMNs are incubated for 3–4 h with mitogens or pathogens leaving non-stimulated controls. Afterwards, a fixation step should be performed and either DAPI staining (Ladero-Auñon et al., 2021) or other DNA intercalating staining with Sytox Orange (von Köckritz-Blickwede et al., 2010) can be used to assess ETs. However, since DNA is not the only component in ETs, immunostaining of specific additional ET elements can aid in the visualization of these structures and therefore proper immunocytochemistry staining for histones (Ladero-Auñon et al., 2021) or myeloperoxidase (MPO) (von Köckritz-Blickwede et al., 2010) or NE (Conejeros et al., 2019) can be performed.

Immunocytochemistry is encouraged if quantification is the goal. An example of a quantification pipeline reported by Ladero-Auñon et al. (2021) can be to take snapshots of a representative number of fields containing visible ETs as seen in Fig. 5A–D, with

Fig. 5 Neutrophil extracellular trap (NET) assessment by microscopy of bovine neutrophils against *Mycobacterium avium* subsp. *paratuberculosis* (Map)-GFP example. (A) DAPI, (B) histone, (C) Map-GFP, (D) merged, (E) Red channel converted to 8-bit, (F) Threshold adjusting to 5-255, (G) Mask of SIZE: 0-INF Circularity 0-1, (H) Mask of SIZE: 100-INF CIRCULARITY: 0.1-1, (I) Mask using the freehand section tool for the nuclei that cannot be chosen with the previous automatic method and measure adjusting SIZE: 0-INF Circularity 0-1, (J) Measurement data of (G, H, I, K) Threshold 0-255, (L) Mask and measurement of the total area of the picture adjusting 0-INF Circularity 0-1.

histone staining (Fig. 5B) and then analyze the snapshots in 8-bit format (Fig. 5E) using the Image J software package. Threshold should be adjusted depending on the micrograph (Fig. 5F) and then a masks must be set (Fig. 5G–I) and measured (Fig. 5J) so that the percentage of picture area occupied by ETs plus nuclei (total DNA) can be measured by adjusting the settings for fluorescent particle size and the percentage of picture area occupied by nuclei can be analyzed. The % of area in G and H is automatically calculated, whereas the total area of the picture needs to be calculated adjusting the threshold of the picture from 0 to 255 (Fig. 5K) and measuring the particles as 0-INF Circularity 0–1 (Fig. 5L).

Afterwards, ET percentage can be calculated as total DNA percentage minus nuclei percentage. In the case of cultures that do not contain ETs, nuclei can be measured, and ET release should be considered zero.

Measuring the killing effect of NETs

What takes PMNs to release NETs or to phagocytose pathogens is not clear (Ley et al., 2018) and many microorganisms have not been tested yet for their ability to stimulate NET release. Also, NETs can be beneficial or harmful for the host as mentioned before. In any case, NETs can be liberated but their microbiocidal or cytotoxic effect is not really evaluated when NETosis assays are performed. It has been shown that NETs impede cancer cell growth by inducing apoptosis and/or inhibiting proliferation (Arelaki et al., 2016; Schedel et al., 2020). Also, NETs have shown to inhibit tumor cell migration (Schedel et al., 2020).

For this purpose, *ex vivo* generated NETs can be isolated from cultures and added to pathogens or tumor cells (Arelaki et al., 2016) to study their effect on growth. Adding DNA extracted from non-activated PMNs can serve as a control.

Other markers of NETosis

PMNs are reactive cells, and sometimes isolation methods cannot be achieved because alterations in cell functions are produced or *ex vivo* cell assays cannot be performed for other reasons, such as sample availability. In these cases, techniques measuring other biomarkers such as MPO and NE can be helpful and supportive of PMN activity. MPO can be liberated by PMNs through degranulation or by cell-death pathways such as apoptosis and necrosis but also via the extrusion of NETs. NE is a neutral serine protease normally expressed in PMN primary granules that stimulates mucus secretion and induces CXCL8 release from epithelial cells and can perpetuate the inflammatory state. NE is able to degrade virulence factors of Gram-negative bacteria (Weinrauch et al., 2002) and destroy host tissue and it is also found in NETs.

MPO-DNA and NE-DNA complex ELISA

Over the past years, estimating MPO or NE associated to DNA, this is MPO-DNA and NE-DNA complexes, have been considered specific quantifiable markers of in vivo NETosis (Masuda et al., 2016). Therefore, these complexes can be quantified in serum by a capture enzyme-linked immunosorbent assay (ELISA) (Kessenbrock et al., 2009; Yoo et al., 2014), which involves the coating of microtiter plates with anti-MPO or anti-NE antibody. Once a blocking step is performed, serum samples are added for incubation and after washes are performed a horseradish peroxidase (HRP)-conjugated anti-DNA antibody is added. Washes to eliminate extra not specifically bound HRP-conjugated anti DNA antibody are performed and HRP substrates are added for the development of color and the ELISA is read.

Although standardization is needed and this methodology has been recently questioned for its specificity in serum samples (Hayden et al., 2021) the truth is that this method is widely used. If possible, before selecting this method as a sole measure of NETosis for new studies it should be performed in parallel to a proper *ex vivo* NETosis assay with isolated PMNs or other techniques seeking for correlation.

Conclusions

PMN research has greatly increased in the last decades changing our view on this immune cell type. The fact that PMNs have shown different phenotypes and that they perform many more functions than those strictly considered as antimicrobial have indeed revitalized the learning of PMN biology. Performing functional assays has been crucial to pathogenesis studies and vaccine development but also to support the finding that PMNs are trainable immune cells. Future research should probably cover the assignment of particular PMN phenotypes to each specific function as well as delving in their role in trained immunity aimed at discovering new therapies.

The natural killer (NK) cells - basic information

a. Origins

The NK cells are currently recognized as one of the innate lymphoid cell (ILC) type and the only one with cytolytic properties and ubiquitous, while other ILCs are mostly confined to mucosal tissues and do not show cytotoxic capabilities. As all the lymphoid cells, the NK cells originate as a progeny of the hematopoietic stem cells (HSC) in the bone marrow (BM).

b. Morphological/phenotypic characteristics

The NK cells are described as so-called large granular lymphocytes or LGL, which suggests their basic lymphocyte morphology (round with roughly spherical nucleus), and diameter (as seen in classical blood smears on microscopic slides) slightly larger than that of average lymphocyte. Still, the latter does not allow for simple detection of the NK cells by flow cytometry using standard forward and side scatter, as they remain within the characteristic lymphocyte cluster in the two-dimensional dot plots. In fact, diameters of lymphocytes are measured (by FACS, particle analysis, microscope planimetry and transmission electron microscopy) as 5.0–11.0 µm corresponding to roughly spherical volume of 142–265 fl; the NK cells fit within this range.

How can they be differentiated from other lymphocytes then? First, the NK cells possess a unique surface phenotype (detectable by e.g. immunocytochemistry and quantifiable by FACS), consisting of lineage marker molecules CD56 and CD16 (FcγRIIIA, a class of receptors for immunoglobulin G heavy chain fragment Fcγ), lacking the molecules characterizing the T cells (CD3) or B cells (CD19), and expressing characteristic function-associated surface proteins, including activating and inhibitory receptors. In more detail, changing phenotypes of the NK lineage cells are associated with stepwise acquisition of killing properties and include up to 6 stages of differentiation. Their differentiation from other lymphocytes is multistage; stage 1 consists of the CD34⁺CD45RA⁺ HSCs in the BM, stages 2, 3 and 4 happen in tonsils, spleen and lymph nodes and involve the consecutive acquisition of CD56, CD117 and IL-1R1 (stage 2), the loss of CD34 characterizing the early HSC in the BM (stage 3) and finally the downregulation of CD117 with concomitant expression of CD94, which defines the earliest functional CD56^{bright}CD16⁻ NK cells (stage 4) (Quatrini et al., 2021). At this stage the NK cells express relatively high levels of T-BET and EOMES, two transcription factors required for them attaining functional “killer” capabilities, notably the production of perforins and granzymes A and B (belonging to serine proteases) used in the target cell killing process in the NK cells in stage 4b, the first stage of the NK cell development associated with their, so far relatively less efficient, killer function. These functionally important NK cell proteins are enclosed in the characteristic granules of the NK cells (earning them the name of large granular lymphocytes or LGLs) which can be visualized by appropriate staining techniques in both light and electron microscopy. Stage 4b is additionally differentiated from immediately preceding stage 4a by expression of NKP80. Partial loss of the surface CD56 molecules and acquisition of the CD16 marks the stage 5 (CD56^{dim}CD16⁺) of most efficient natural killers. These NK cells also express the surface killer Ig-like receptors (KIRs), important for the ability of NK cells to detect and kill their targets. Finally, additional expression of the CD57 characterizes the terminally differentiated NK cells in their stage 6 of differentiation or indicates an activation state.

However, these phenotypic stages are apparently not distinguishing functionally different NK cells in a sharp way, but more in a “fuzzy” way, putting in question the linear model of NK cell differentiation described above and proposing an alternative, branching one (Poznanski and Ashkar, 2019). Thus, in the latter a special type of the NK cell precursor was identified in the BM having the phenotype of Lin⁻CD34⁺DNAM1^{bright}CXCR4⁺ (Bozzano et al., 2015). This precursor may differentiate in either CD56^{bright}CD94⁺KIR⁺ NK cells, which later transform into the more mature CD56^{dim}CD16⁺KIR⁺ cells. The latter may form either the terminally differentiated CD57⁺ NK cells or acquire the phenotype of KIR⁺NKG2C⁺CD57⁺ and become capable of controlling the CMV infection in a memory-like fashion, earning them the name of “adaptive NK cells” (Bozzano et al., 2021a; Muntasell et al., 2013). To make the development of NK cells even more complex, these “adaptive NK cells” may, according to this model, derive straight from the Lin⁻CD34⁺DNAM1^{bright}CXCR4⁺ precursor (which appears to also be the precursor for the

T cells) (Bozzano et al., 2015). Eventually, also the “fully” lymphoid lineage origins of the NK cells are questioned, as the CD56^{bright}CD16[−]CD94⁺ NK cells may arise from a *myeloid precursor* with the phenotype CD33⁺CD56⁺ (Bozzano et al., 2021a, 2015; Scoville et al., 2017).

c. Function/role (what and how do they kill?)

The NK cells evolved to recognize and kill own cells that have been modified in one of the two, potentially dangerous and deadly ways: either by undergoing neoplastic (eventually malignant) transformation or by hosting the replicating viruses. The latter is true also in the context of current (2021) pandemics of COVID-19 due to infection by SARS-CoV-2 coronavirus (Bozzano et al., 2021b). Either modification leads to the appearance of new characteristics. In the former (cells turning neoplastic) we assist to the appearance of new antigens (surface and cytoplasmic neoantigens) being the effect of transforming mutations; in the latter the presence of viral antigens also makes them foreign (non-self). In order to ascertain the long(er) survival of virus-infected organism (or of that in which some cells undergo potentially cancerogenic mutations) both these unwanted cell types must be effectively recognized, differentiated from the neighboring healthy cells, and killed before their “mass effect” will hamper the functions of the organism.

Even if both the transformed and virus-infected cells are the source of antigens, these are the objects of interest of adaptive immunity T and B cells and rely on the specificities of respective antigen receptors (TCR and BCR). The NK cells recognize the transformed or infected cells using a different detection mechanism. Thus, they may be activated (primed for killing) by two groups of surface ligands present on the potential target cells; the first one consists of different classes and variants of the HLA-I histocompatibility antigens, including the HLA-A, HLA-B851, HLA-C C1, HLA-C C2, HLA-F; the second group of target cell molecules activating the killing frenzy of the NK cells is more heterogenous and consists of the FcIgG, B7, BAT3, CD48, CD58 and many other (Table 1) (Carrillo-Bustamante et al., 2016; Pende et al., 2019; Sivori et al., 2020; Quatrini et al., 2021).

Viral HA and complement factor P (properdin, binding the NKp46) are main molecules derived from or responding directly to the infecting agents that elicit the NK cell activation. As it is easy to perceive, most (with the exception of neoantigens and viral peptides) molecules that can activate the NK cells are nonspecific and can be present on any healthy cell type; it would be highly undesirable that they would induce NK-dependent killing of normal cells. Thus, evolutionary constraints were imposed in the form of sets of similar, but NK cell-inactivating (inhibitory) molecules. Again, they may belong to the broad family of HLA-I antigens (in fact, some of these serve as activators or inhibitors of the NK cell killing, depending on what will be the NK cell receptor binding them (Table 1). Other again form a heterogenous group of ligands. Interestingly, also some molecules belonging not to the cells, but to the extracellular matrix (ECM), including collagen, may exert an inhibitory activity.

Table 1 Known activating and inhibitory NK cell receptors and their recognized ligands on target cells.

Activating HLA-I specific NK cell receptor	Target cell ligand	Inhibitory HLA-I specific NK cell receptor	Target cell ligand	Activating NON- HLA-I specific NK cell receptor	Target cell ligand	Inhibitory NON- HLA-I specific NK cell receptor	Target cell ligand

For clarity, the receptors are divided into HLA-I specific (left panels) and HLA-I non-specific (right panels).

Based on Pende D, Falco M, Vitale M, Cantoni C, Vitale C, Munari E, Bertaina A, Moretta F, del Zotto G, Pietra G, Mingari MC, Locatelli F, and Moretta L (2019) Killer Ig-like receptors (KIRs): Their role in NK cell modulation and developments leading to their clinical exploitation. *Frontiers in Immunology* 10: 1179; Quatrini L, Della Chiesa M, Sivori S, Mingari MC, Pende D, and Moretta L (2021) Human NK cells, their receptors and function. *European Journal of Immunology* 51: 1566–1579; Sivori S, Della Chiesa M, Carlomagno S, Quatrini L, Munari E, Vacca P, Tumino N, Mariotti FR, Mingari MC, Pende D, and Moretta L (2020) Inhibitory receptors and checkpoints in human NK cells, implications for the immunotherapy of cancer. *Frontiers in Immunology* 11: 2156; Carrillo-Bustamante P, Kesmir C, and de Boer RJ (2016) The evolution of natural killer cell receptors. *Immunogenetics* 68: 3–18.

Killing of the neoplastic or virus-infected cells occurs either by induction of extrinsic pathway of apoptosis or by lysis (Sordo-Bahamonde et al., 2020). The former depends on binding of death ligands FasL/CD95L present on the NK cells and TRAIL (on resident liver NK, but not on peripheral blood NK cells) to cognate TNF-family death receptors including the Fas/CD95 and is caspase-dependent (von Karstedt et al., 2017). On the other hand, lysis of target cells attacked by the NK lymphocytes is executed by the contents of characteristic granules of the NK cells, including perforin, granzymes A and B, and granulysin, released into the intercellular space between the NK and target cell enclosed by the immune synapse. Tight connection of the two cells prevents the spillage of above mentioned proteins and damage to neighbor cells. Perforin (PRF1) is a glycoprotein which inserts in the membrane of target cells and oligomerizes there, forming a pore. This by itself adversely affects the osmotic balance within the target cell, eventually leading to its lysis. PRF1 pores are also the gates for proteases (granzymes) which stimulate apoptosis of target cells by truncating the caspase-8-activated Bid protein and, mainly, converting procaspases 3, 6 and 7 into their active forms (granzyme B) and by leading to the damage of target cell DNA in a caspase-independent way (granzyme A (GZMA) increasing production of ROS by mitochondria which stimulates SET complex translocation from the endoplasmic reticulum to the nucleus, where SET itself is cleaved by GZMA, leading to the release of DNA-degrading nucleases, such as NM23-H1 DNase) (Sordo-Bahamonde et al., 2020; Kiselevsky, 2020).

Metabolism and functionality

Some recent papers indicate that the phenotypes of NK cells as described above do not fully correspond with their different functionalities. Thus, it has been shown that cytotoxic NK cells can display not only their classical CD56^{dim}CD16⁺ phenotype, but may also be CD56^{bright} and yet even more cytotoxic than the classical ones. On the other hand some regulatory NK cells, classically defined as CD56^{bright}CD16⁻, can also express CD16. Finally, the memory NK cells may be either CD56^{bright} or CD56^{dim} and CD16⁺ or CD16⁻. Furthermore, even the nominally function-associated receptors: Natural Cytotoxicity Receptors (NCRs), NKG2A, NKG2C, KIRs, and CD57 may be expressed at low or high level (or not at all) on any NK cell, whether cytotoxic, regulatory or memory. Summarizing, even the NK cells with opposing functions can express the same phenotypes indicating a certain plasticity in the phenotype for performing the needed function depending most probably from the microenvironment (Poznanski and Ashkar, 2019).

One needs to remember, that the NK cells are not just killers of pathologically modified cells. Apart from performing anti-tumor and anti-viral functions, they regulate the functions of other immune cells and even promote tissue growth by secreted cytokines (Vivier et al., 2008; Vitale et al., 2019). The latter may result in actually promoting the tumor growth rather than preventing it (Crome et al., 2017; Bruno et al., 2013; Levi et al., 2015). Other non-killer functions of the NK cells include participation in the growth of placenta and tolerance of fetus during pregnancy (Gamliel et al., 2018; Hanna et al., 2006; Ashkar et al., 2000).

The apparent phenotypic chaos makes any interpretation of surface phenotypic analysis (e.g. by flow cytometry or IHC) of the NK cells in the context of their adequate or pathological functions very doubtful and asks for other determinants of these functions. Growing body of evidence suggests that it might be differences in cellular metabolism, mainly glucose-driven glycolysis and oxidative metabolism which drive the NK cell development, education, effector functions and generation of NK memory cells (Schafer et al., 2019; Cichocki et al., 2018; Holmes et al., 2021; O'Sullivan et al., 2015). Thus, activated cytotoxic NK cells increase both glycolysis and OXPHOS and it was found that higher capacity for glucose metabolism (both glycolysis and OXPHOS) identifies the NK cells with the highest cytotoxic capabilities. Conversely, NK cells become regulatory under low levels of glycolysis and OXPHOS and likely utilize fatty acids and/or amino acids as energy sources. Finally the memory NK cells exhibit increased mitochondrial fitness, resulting from extensive mitophagy. These cells show an increased spare respiratory capacity (SRC) and mitochondrial membrane potential and manufacture less reactive oxygen species (ROS) (Poznanski and Ashkar, 2019).

Aging-related and other defects of NK cell functions

As all the other long-living cells of the immune system, also the NK cells undergo aging. Aging of this part of the immune system manifests both as changes in the proportions of cells exhibiting different phenotypes described above, and as functional changes within specific phenotypes (reviewed by Witkowski et al., 2020). Thus, the percentage of NK cells among the PBMC of healthy old individuals and centenarians is increased, but the CD56^{dim}CD16⁺ population of these cells expands at the expense of the CD56^{bright}CD16⁻. The decreased proportion of the former may be the reason for decreased overall production of cytokines and chemokines by activated NK cells of elderly. On the other hand, the remaining CD56^{bright}CD16⁻ NK cells of old individuals tend to manufacture more granzyme A and IFN, which is considered a compensatory mechanism aimed at the maintenance of the protective and immunoregulatory roles of these cells in elderly. Expanding CD56^{dim}CD16⁺ NK cells of the elderly exhibit decreased amounts of granzyme A, but not granzyme B or perforin; thus, their cytotoxicity as a population is sustained. However, if considered at the single cell level, the NK cells of old individuals are less capable of killing virus-infected or transformed cells, which translates clinically to decreased resistance to viral infections and cancers. The reason behind these individual cell level changes associated with aging may be changes in expression and in consequence function of various NK cell specific receptors, including decrease of some activating receptors like Nkp30 and Nkp46, and concomitant increase in the expression of inhibitory KIR and a decrease in CD94/NKG2A. Other aging-associated changes in the phenotype of peripheral NK cell population include increased proportion of terminally differentiated, highly cytotoxic but feebly proliferating CD57⁺ lymphocytes. Interestingly, such phenotypic shifts in NK cell population are also described as resulting from chronic viral infections, notably by the CMV.

One additional function of the NK cells which is likely affected by their aging leading to shorter healthspan is their ability to detect and destroy the senescent cells, accumulating with advancing age in all tissues. In fact it is possible that the accumulation (increased proportions) of senescent cells observed in the tissues of old individuals (and its consequences for functioning of various organs in the elderly) are mainly due to decreased functional capabilities of the NK cells in these individuals (Baker et al., 2011; Ovadya et al., 2018; Sagiv et al., 2013; Pereira et al., 2019).

As mentioned above, function of different NK cells is defined not only by their distinct phenotypes, but by associated metabolic characteristics and its differences (decreased OXPHOS versus increased aerobic glycolysis, changes in use of glucose or of fatty acids as energy sources etc.). In the aged, senescence of the NK cells is associated with no OXPHOS to aerobic glycolysis switch upon activation (including by IL-2), and no increase in mitochondrial mass and functions, which may be responsible for decreased global effector functions of NK cells from older individuals (Miranda et al., 2016, 2018).

Means of detection and quantification of the NK cells in the peripheral blood

Currently the golden standard for detection, identification and quantification of various populations of the NK cells is multicolor flow cytometry after most frequently a separation process for the blood mononuclear cells including also monocytes and lymphocytes. It allows not only for identification of cells being positive or negative for a given marker (defining the proportion of such positive cells in a population), but also makes possible measuring the level of fluorescent signal from a marker, which can crudely define cells as negative, dim, and as positive, bright with regard for this marker (e.g., CD56^{dim} or CD56^{bright} NK cells) which, as said above, might translate to different functions of the respective populations. However, there are already quite old techniques allowing for cytometric determination of actual numbers of molecules of interest on the cell surface (quantitative flow cytometry using the QuantiBrite™ system (BD Biosciences, San Jose, CA)), from as few as 20–30 per cell to as many as 10⁵ and more, with the help of proper standards. We have shown for molecules like CD28, TNF receptors TNFR1 and R2 or EpoR that their numbers on the surface of a T cell correlate with levels of its response to stimulation; to date, similar analyses have not yet been performed for various receptors on the NK cell surface, but likely they could yield interesting results (Bryl et al., 2005; Witkowski and Bryl, 2004; Lisowska et al., 2010, 2011). Monoclonal antibodies against most if not all the surface antigens characterizing different NK cells have been generated and, with appropriate choice of attached fluorochromes, allow for simultaneous surface characteristics of all the peripheral blood leukocyte types (and so allowing for finding of potential correlations between changes in different leukocyte populations) (Sahir et al., 2020). In one recent work 8 out of 40 markers (CD56, CD16, CD2, NKG2D [CD314], NKP30 (CD337), NKG2A (CD159a), NKG2C (CD159c), CD57) identified the NK cells and their populations, while the other 32 characterized the T cells, NKT cells, B cells, monocytes, and dendritic cells (Park et al., 2020). The same number of the NK cell antigens was detected by an earlier panel, again aimed at characterizing the full complement of peripheral blood leukocytes (Ruhle et al., 2016). However, currently the full power of multicolor flow cytometry, spectral flow cytometry or mass cytometry (CyTOF™, where the antibodies are labelled with heavy metal ion tags rather than with fluorochromes) may allow for simultaneous detection of many more antigens on a surface of a NK cell (theoretically more than a hundred different markers per cell in case of currently (mid-2021) available reagents). It goes without saying that determination of various NK cell antigens may be performed at rest and upon activation (either in vitro or due to specific clinical circumstances, including cancer development or viral infection) and so allows for comparison of the resting and activation-dependent receptor patterns, also in the context of other leukocyte populations.

Means of detection and quantification of NK cells in tissue samples

The NK cells reside and can be detected in various human tissues, including the liver, brain, tonsils, lungs, skin, intestine, uterus, and heart (Marquardt et al., 2015, 2017, 2019; Cheuk et al., 2017; Brownlie et al., 2021; Masopust et al., 2010; Vento-Tormo et al., 2018; Sun et al., 2021; Sedgwick et al., 2020). It is unclear if the NK cells found in the tissues are the permanent residents or are drawn into the tissue by some process leading to signals (like cytokines and/or chemokines) being released. Clearly, NK cells infiltrating the tissue are equipped with a complement of adhesion molecules (integrins) and chemokine receptors deciding about their tissue targets (Hegewisch-Sollosa et al., 2021). One surface marker of tissue-residing NK cells is the CD49a which normally is not expressed by circulating NK cells; recently however small populations of the NK cells with the phenotype CD49a⁺KIR⁺NKG2C⁺CD16⁻ were found in the peripheral blood of individuals in whom this population expanded in the lungs due to activation (Brownlie et al., 2021).

Detection of tissue-resident NK cell populations may be achieved by two major methods: immunohistochemistry (IHC) and flow cytometry. Both have their advantages and some disadvantages.

The IHC allows for determination of distribution of the NK cells within the tissue of interest, e.g., showing their preferential infiltration near tumors and in the virus-infected organs. Fluorescent confocal microscopy allows to detect the immune synapses between the NK cell and its target. On the other hand it is currently not possible to stain and visualize more than a few NK cell antigens in a single tissue sample, so deep IHC analysis of the composition of different functional populations of NK cells in a studied tissue is difficult. Also the quantification of these NK cells is usually limited to counting them as a proportion of total lymphocytes seen in the specimen and may be biased by uneven distribution of the cells in the tissue sample. Finally, control

("negative") slides attained e.g. with irrelevant antibodies are rarely used, and in the fixed and slice tissue the antibodies gain access to the cell interior and may bind there both to the relevant antigens which are on their way to the cell surface and non-specifically. Both of these may lead to false positive results.

Flow cytometry analysis of the phenotypes of tissue-resident cells (including the NK lymphocytes) cannot, of course, provide the topographic information about the distribution of various NK cells in the tissue, as the tissue of interest must be converted to a suspension of free cells prior to staining and analysis. This is achieved by proteolytic disintegration of matrix by collagenases and by prevention of the cells being glued together by DNA released from those damaged in the tissue processing using the DNases (Brownlie et al., 2021). Such unicellular suspension is then centrifuged in a density gradient (using the same reagents that are used to obtain the peripheral blood mononuclear cells) in order to obtain the suspension enriched in mononuclear leukocytes including the NK cells. These then undergo the same staining and FACS analysis as the PBMC, yielding the numbers (expressed per milligram of wet tissue or per mm³) and proportions of different NK populations in a given tissue sample.

Means to estimate functional capabilities

a. testing secretion of perforins and granzymes

Both perforins and granzymes GZMA and GZMB are preformed and stored in the characteristic granules of the resting NK cells, to be released upon activation (Lettau et al., 2015). As both are proteins, they can be detected in fixed/permeabilized NK cells with appropriate fluorescent antibodies and flow cytometry, which allows for comparison of relative amounts of these proteins between different NK cell populations (identified by their characteristic receptors) in a sample and between samples (e.g. derived from different individuals with diversified states of health and diseases). Recently it has become possible to actually measure the proteolytic activities of granzymes while in the granules, using specific protease-cleaved fluorogenic substrates, relevant granzyme inhibitors and flow cytometry (Janiszewski et al., 2020; Kolt et al., 2020). Upon activation in and by the presence of cognate target cells both granzymes and perforin are secreted into the space between the NK and target cell enclosed by the immune synapse which can also be detected and visualized (Friedman et al., 2021; Ambrose et al., 2020). Amount of secreted PRF1 and GZMs may also be measured in in vitro cultures of purified NK cells with appropriate soluble stimulants including IL-2 or the cocktail of phorbol myristate acetate (PMA) and calcium ionophore ionomycin; in this case the proteins are released into the culture medium and can be quantified e.g. by ELISA.

b. testing the killing of target cells in vitro

Killing of the compromised (transformed or virus-infected) cells is the most obvious function of the cytotoxic NK cells and its modified effectiveness may lead to uncontrolled virus infection or cancer spread (if the function is decreased) or to attack on own cells and development of autoimmunization and autoimmune diseases including type 1 diabetes or systemic sclerosis if the same killing function is above normal.

The effectiveness of the killing process can be assessed for the NK cells upon their purifying (elimination of other cytotoxic/cytolytic cells like the NKT and cytotoxic CD8+ T cells) by either magnetic or FACS sorting. Numbers of killed target cells (e.g. K562 erythroleukemia routinely used for such determination, or more specific targets like isolated cancer cells from clinical samples or specific virus-infected cells) may be counted by flow cytometry upon their staining with e.g. membrane integrity-dependent DNA dyes like propidium iodide or 7-amino-actinomycin D (7-AAD). This is relevant, as the NK cell killer activities result mainly in the induction of target apoptosis and the above mentioned stains are routinely used for quantifying apoptotic cells. These numbers of killed target cells may be expressed per a killer NK cell at different effector:target ratios on condition that the latter are properly detected (e.g. as CD3-CD56+CD16+/-, with possible addition of activation receptors CD25 and/or CD69) and quantified. The use of flow cytometry on one hand allows for simultaneous identification of different phenotypes of both effector and target cells, observation of apoptotic death of the latter and its quantification. On the other hand it makes historically developed methods of NK cell killing activity (like radioactive chromium Cr⁵¹ release from preloaded target cells or the release of lactate dehydrogenase from the targets upon incubation with the NK cells) obsolete. The only technique of NK cell-dependent killing of target cells based on their preloading with a detector reagent remaining is the use of calcein-AM loaded targets which release calcein (and become less fluorescent) upon being attacked by the NK cells; this process can be visualized and partially quantified by imaging cytometry (McCulley and Somanchi, 2016; Somanchi et al., 2015).

c. testing secretion of cytokines and chemokines

As mentioned above, the NK cells, apart from being effective killers of compromised cells, perform multiple regulatory functions affecting other immune cell types (Zwirner et al., 2021; Vitale et al., 2019). These functions generally depend on secretion of interferons and other cytokines and chemokines by activated NK cells, including: tumor necrosis factor- α (TNF- α), interferon γ (IFN- γ), IL-5, IL-10, IL-13, GM-CSF, and the chemokines MIP-1 α , MIP-1 β , IL-8, and RANTES (Fauriat et al., 2010). These regulatory molecules may be detected either in the cytoplasm of the NK cells by flow cytometry (after stimulation with blocked secretion to allow for cytokine accumulation, fixation/permeabilization of the membrane and staining the accumulated cytokines with appropriate, fluorescently tagged monoclonal antibodies). This technique allows for simultaneous phenotyping and quantification of the NK cells producing cytokines of interest upon contact with target cells or other means of activation. Alternatively, cytokines of

interest already released from in vitro activated NK cells may be detected and quantified in the culture media by ELISA or by flow cytometric technique using polystyrene microbeads with conjugated anti-cytokine antibodies to capture the cytokines and fluorescently tagged antibodies to detect and quantify bead-bound cytokines (cytokine bead assays, CBA™). The latter technique allows for multiplexing, i.e., simultaneous detection of up to 30 different cytokines from a single sample (Castillo and MacCallum, 2012).

We described presently separately the determination of phenotypes and functions. However with the recent progresses in the multi-omics measurements it will be more and more easy and common to perform single cell studies including the phenotypes, the functions, the transcriptomic, the epigenomic and the genomic. This will help to better characterize, to understand and to target the NK cells during health and disease (Zhou et al., 2017; Zhang et al., 2021).

d. testing NK metabolism

As mentioned above, NK cells' phenotype assessment, even multiparameter and deep, is by itself not a reliable way to assess the NK function, due to marker overlaps. As also mentioned above, it was repeatedly demonstrated that activation of the NK cells depends on their metabolic changes, including the increase of both glycolysis and OXPHOS (Cong, 2020; Keating et al., 2016). These processes can currently be measured as extracellular acidification rates (ECARs) and oxygen consumption rates (OCR) in purified NK cells and their subpopulations with devices like the XF-24 Extracellular Flux Analyzer (Seahorse Bioscience) (Keating et al., 2016; Assmann et al., 2017; Donnelly et al., 2014). Sequential measurements of ECAR and OCR, following addition of the inhibitors: oligomycin, rotenone, antimycin, and 2DG, allow for the accurate calculation of oxygen consumption due to oxidative phosphorylation (OXPHOS) and acidification due to glycolysis (Assmann et al., 2017).

Summary

The NK cells are among the most important innate cells of the immune defense system. They are very heterogeneous in their phenotypic appearance and in their functionality which will certainly increase with the advances of our knowledge. There are several described techniques to unravel their diversity and functionality either in the blood or in the tissues. However, these classic tests are meant to evaluate and be included in a complex system approach using the combination of several levels of study in a multi-omics manner with the help of the artificial intelligence either at the single cell or cell population level. These new methods and concepts will help to integrate the individual techniques in a complex system for better assessment of the NK biology in health and disease.

The complement system

The complement system is well known as a key component of the innate immune system. Its functions comprise: (1) the elimination of microbes (through cytolytic membrane attack by disrupting bacterial cell walls), (2) the removal of apoptotic cells and debris (through opsonization of antigens to promote phagocytosis), (3) to evoke an inflammatory response (through recruitment and activation of leukocytes, particularly macrophages and neutrophils), and (4) the modulation of the adaptive immune response through modification of T- and B-cell responses, employing specific receptors on various immune cells (Holers, 2014; Brodzski et al., 2020). Moreover, a normally functioning complement system also participates in hematopoiesis, reproduction, lipid metabolism and tissue regeneration (Merle et al., 2015). Only recently, intracellular functions of the complement system have been discovered modulating T lymphocyte activation and survival (Arbore et al., 2017).

Most complement proteins are secreted by the liver and contribute to the acute phase response. However, other tissues like the kidney are also able to produce complement proteins to a significant amount (Poppelaars and Thurman, 2020). Complement genes are distributed across different chromosomes, with 19 genes comprising three significant complement gene clusters in the human genome (Mayilyan, 2012).

Approximately 50 soluble and cell surface-attached proteins are currently recognized, acting as components, cofactors, regulators and receptors of the complement cascade (Holers, 2014). Unfortunately, the terminology of the complement system components rather refers to the sequence of their discovery than to a logical numeric order within the cascade reaction. Components and regulators of the AP are called factors (e.g., Factor B, Factor H) (Bohlson et al., 2019). Complement can be activated via three major pathways, the classical, the alternative, and the lectin pathway, all of which merge in the activation of complement C3 and subsequently lead to the formation of the cytolytic membrane attack complex (MAC), C5b-9 (Merle et al., 2015) (Fig. 1). To prevent inappropriate complement activation, regulatory proteins play an important role, whether present in the fluid phase or bound to the cell surface (Zipfel and Skerka, 2009). Soluble complement regulators, such as C1 inhibitor, C4b-binding protein (C4bp), Factors H (FH) and I (FI), clusterin and S-protein (vitronectin) restrict the action of complement in body fluids at multiple sites of the cascade (Fig. 1). In addition, each individual host cell is protected against the attack of homologous complement by surface proteins, such as the complement receptor 1 (CR1/CD35), the membrane cofactor protein (MCP/CD46) as well as by the glycosylphosphatidylinositol (GPI)-anchored proteins, decay-accelerating factor (DAF/CD55), and protectin (CD59) (Ling and Murali, 2019).

Complement and diseases

Complement is engaged in a number of diseases (Brodzski et al., 2020) (Table 1). Genetic deficiencies of complement components are rare; their estimated prevalence is about 0.03% excluding MBL deficiency, which is estimated to occur in about 5% of the Caucasian population (Grumach and Kirschfink, 2014). In the European Society for Immunodeficiencies (ESID) registry, deficiencies of complement proteins account for approximately 5% of all primary immunodeficiencies (PID) between 2004 and 2020 (<http://esid.org/Working-Parties/Registry/ESID-Database-Statistics>; <https://cci-reporting.uniklinik-freiburg.de/#/>). However, in national registries a wide variability in the frequencies of complement are reported, ranging between 1% and up to 30% of all primary immunodeficiencies (Abolhassani et al., 2020).

Fig. 1 Complement system: activation pathways, terminal pathway and regulation (blue).

Table 1 Complement mediated diseases and recommended complement analysis.

Disease	Complement testing
Infectious diseases	CP-, AP-, LP assay, C3, C4, C1q C3a/C3d, sC5b-9 C5-C9, P; MBL (especially in <i>Neisseria</i> infections)
Systemic lupus erythematosus, hypocomplementaemic urticarial vasculitis syndrome	CP analysis C4 (C4A/B), C1q, C3 C3a/C3d, sC5b-9 Anti-C1q autoantibodies
Angioedema	C1 inhibitor (protein and function) C4, C1q Auto-Anti-C1 Inh (acquired angioedema)
Nephropathies (C3 glomerulopathy/DDD*/aHUS**)	CH50, APH50 C4, C3 C3a/C3d, sC5b-9 Factor H, Factor I *C3 (and C5) nephritic factor **Autoantibodies to factor H, factor B, C3 convertase molecular analysis of CFH, CFI, C3, FB, CD46
Paroxysmal nocturnal hemoglobinuria	CD55, CD59 (FACSCAN) Acid lysis test

Complement defects, particularly of early components of the classical pathway, are frequently associated with autoimmune disorders, esp. with systemic lupus erythematosus (SLE). There is a strong association of a complement deficiency with SLE increases from C2 (10% prevalence) over C1r/s (57% prevalence), C4 (75% prevalence) to C1q (90% prevalence) (Pickering et al., 2000).

Warning signs for complement deficiencies are (1) Meningococcal meningitis at >5 years of age, (2) other recurrent bacterial infections, esp. with *Pneumococcus*, (3) autoimmune manifestations, (4) angioedema without urticaria, (5) renal and ophthalmic inflammatory disorders, (6) unusual infections, e.g., epiglottitis despite vaccination against *Haemophilus influenzae* type b (HIB) and, (7) severe infection with encapsulated bacteria (Grumach and Kirschfink, 2014; Brodzski et al., 2020).

In clinical practice, however, the consequences of an overactivated complement system with consumption of complement components as the cause of several inflammatory diseases and even life-threatening conditions are more prevalent (Prohászka et al., 2016; Ekdahl et al., 2018). The sudden exposure to a massive altered self or foreign particles, as in the case of sepsis or trauma, can overwhelm the system and fuel a vicious cycle that causes tissue damage and systemic inflammation. Similarly, transplants or biomedical materials often trigger an adverse complement response that affect both the clinical and functional outcome of the treatment (Ricklin et al., 2017). The kidney appears particularly vulnerable to complement-mediated injury and it was one of the first organs identified as a target of complement-mediated inflammation. Immune-complexes activate the classical pathway of complement in many forms of glomerulonephritis and alternative and lectin pathways are also activated in several forms of kidney disease. Atypical hemolytic uremic syndrome (aHUS) or age-related macular degeneration (AMD) are consequences of local dysregulation of the alternative complement pathway (Prohászka et al., 2016; Poppelaars and Thurman, 2020). The production of certain complement proteins and other acute phase reactants is augmented by inflammatory cytokines, such as tumor necrosis factor alpha, interleukin (IL)-1, and IL-6, which are produced by leukocytes (e.g., macrophages and neutrophils) (Holers, 2014; Ling and Murali, 2019).

Complement analysis

In the last years, modern complement analysis in body fluids and biopsies, going far beyond the detection of C3 and C4 levels, has not only significantly enhanced our current understanding of the disease process, but today also allows for a more precise differential diagnosis (for detailed reviews see: Ekdahl et al., 2018, Prohászka et al., 2016, Prohászka et al., 2018; Schroder-Braunstein and Kirschfink, 2019, Ling and Murali, 2019, Skattum, 2019). This has paved the way for a specific complement-targeting therapy which has now been successfully introduced in patients with various complement-mediated inflammatory disorders (Table 1).

Complement analysis aims at to

- (1) screen total complement activity;
- (2) quantitate individual complement components;
- (3) measure functional activity of individual components;
- (4) quantitate complement activation products;
- (5) detect autoantibodies to complement components or complexes;
- (6) assess cell surface expression and tissue deposition of complement components, regulators or fragments.

Sample collection

Improper handling and/or prolonged transport time at room temperature may affect data interpretation. Another important measure to prevent ex vivo complement activation, serum and EDTA plasma have to be separated from blood cells as rapidly as possible. On receipt, blood samples should be centrifuged as soon as possible and must be kept cold until they are frozen at -80°C until assayed or shipped on dry ice to specialized laboratories (<http://www.ecomplement.org/european-complement-labs.html>). EDTA-plasma is needed for analyses of activation products, while serum is suitable for analysis of complement proteins, function and autoantibodies. EDTA prevents further activation by chelating Ca^{2+} and Mg^{2+} thereby blocking the function of the C1 complex and of the two C3 convertases, respectively. The addition of nafamostat mesilate (Futhan, FUT-175) to EDTA further reduces ex vivo complement activation. For transportation dry ice must be used and the samples should be transferred directly from the -80°C freezer (Nilsson and Ekdahl, 2012). The lack of standardization in complement analysis still poses a major problem to disease recognition and follow-up (Prohászka et al., 2016; Ling and Murali, 2019).

Screening of total complement function

Functional complement activity is traditionally assessed using a hemolytic assay. Activity of the CP is monitored in hemolytic assays employing sheep erythrocytes coated with rabbit antibodies, preferably purified IgM (or mixed with IgG) to the Forssman antigen. Addition of serial serum dilutions of serum leads to binding of C1q to the immunoglobulins which initiates the formation of the CP C3 convertase. This subsequent activation leads to C5 activation and the assembly of the membrane attack complex which finally results in lysis of the erythrocytes (Ekdahl et al., 2018). A more recent lipolytic test for CP activity allows a better standardization of the activating/target cell. One unit CH50 represents the reciprocal of the dilution at which 50% hemolysis is seen. Similarly, alternative pathway activation can be assessed using rabbit (chicken or guinea pig) erythrocytes, which specifically activate the alternative pathway due to decreased sialic acid content. Here a Mg^{2+} + EGTA containing buffer is added to the patient serum prior to incubation which is needed to chelate Ca^{2+} , thereby inhibiting activation via the CP and LP. Hemolytic assays can be used to detect both deficiencies in individual component as well as depression in complement function caused by consumption of complement components (Ekdahl et al., 2018).

Activation of the AP of complement is monitored in hemolytic assays employing rabbit or guinea pig erythrocytes, which are spontaneous and potent activators of human AP. EGTA which chelates Ca^{2+} and thereby inhibits activation via the CP and LP, is added to the patient serum prior to incubation. Under these conditions the AP C3 convertase is formed on the target erythrocytes, leading to C3 activation and subsequent lysis (Ekdahl et al., 2018). Simplified and more rapid hemolytic assays apply are performed with a fixed serum sample dilution and excess of antibody-coated sheep erythrocytes or rabbit erythrocytes for the classical and alternative pathways, respectively (Nilsson and Ekdahl, 2012).

A missing or greatly reduced activity in either test indicates a primary complement deficiency affecting the classical or the alternative or both pathways, but may also be due to a secondary deficiency caused by increased consumption. Analysis of individual components and regulators provide insight, in which portion of the complement cascade either a lack of function or an (over-) activation occurs. (Fig. 2).

Nowadays, also a simple ELISA-based method is available which allows the assessment of the activity of all 3 pathways. This method is easy to perform and has several advantages compared with the hemolytic assays: it is not dependent on erythrocytes; it covers all three activation pathways and properdin deficiency (often not detected in hemolytic assays) can be diagnosed in the functional AP ELISA. The assay is performed with serum samples and the incorporation of C9 in the terminal complement complex C5b-9 is taken as readout (Prohászka et al., 2016).

Quantification of individual complement components

Individual complement components, quantitated in the past by immunodiffusion, is now mostly measured by nephelometry or turbidimetry (Ling and Murali, 2019). These techniques utilize polyclonal antibodies against the analyte, e.g., C1-INH, C4, C3, or factor B or activation fragments of these proteins (Ekdahl et al., 2018). Membrane bound regulatory proteins such as CD55, CD59, and CD35 (CR1) can be assessed using flow cytometry (Ling and Murali, 2019).

Measuring functional activity of single components

If a functional defect is suspected or needs to be ruled out, the functional activity of a single component can be tested. Sera depleted of the actual component and patient's fresh serum are mixed, to see whether the activity can be restored by using hemolysis as readout (Ricklin et al., 2017).

Quantification of activation products of complement

A reduced functional activity of individual complement components either reflect a deficiency state, or indicate ongoing, consuming complement activation. Since in vivo complement activation is often associated with an acute phase reaction, pathway activities or levels of individual components may stay within the normal range despite ongoing consumption. Consequently, these first level screening methods are not sufficiently sensitive to detect pathologically increased complement activation in vivo.

Fig. 2 Screening of complement deficiencies.

Complement activation products are either split fragments, generated after enzymatic cleavage of certain components, e.g., C4 (C4a, C4b/c, C4d), C3 (C3a, C3b/c, iC3b, C3d), factor B (Ba, Bb) and C5 (C5a), or protein complexes where activated components are bound to their respective regulators, like C1rs-C1-inhibitor, the properdin-containing alternative pathway convertase, C3bBbP, and sC5b-9 (soluble terminal complement complex) (Barnum et al., 2020).

It should also be taken into account that different activation products vary greatly with regard to their in vivo half-life: approximately 0.5 h for C3a and 4 h for C3d,g (Teisner et al., 1983). Since C3d,g is a more robust marker, it is more suitable in routine analysis use while the generation of C3a is often used in clinical studies and experimental settings. Due to rapid receptor binding, the biologically highly active and important C5a fragment has a half-life of approximately 1 min and is difficult to detect in samples obtained in vivo (Oppermann and Götze, 1994). In contrast, the half-life of sC5b-9 is 50–60 min (Barnum et al., 2020).

Formation of the lytic C5b-9 (MAC) complex is the last step of the complement cascade which causes cell damage or lysis as a result of its insertion into the cell membrane, or endothelial cell activation at sub-lytic concentrations. Complement activation of the TP can be monitored in body fluids by quantification of sC5b-9, with an EIA which uses a mAb specific for a neoepitope in C9 for capture (Ekdahl et al., 2018).

Detection of autoantibodies to complement components

Similar to *loss or gain of function* mutations in complement regulators or activating components, an overactivation of complement can also be caused by autoantibodies. Autoantibodies to FH (DEAP-HUS), FB (DDD), C1q (SLE) or to C1 inhibitor (hereditary angioedema) can be assessed by ELISA with the respective purified complement proteins immobilized on a microtiter plate (Defendi et al., 2020).

Nephritic factors comprise a heterogeneous group of autoantibodies against neoepitopes generated in the C3 and C5 convertases of the complement system, causing its dysregulation (Corvillo et al., 2019). C3 nephritic factor (C3NeF), found in all types of MPGN can be measured in a decay assay as C3NeF stabilizes the alternative pathway C3 convertase, C3bBb. In this semi-quantitative screening assay C3NeF stabilizes the C3 convertase on sheep erythrocytes, thereby causing increased complement activation and eventually hemolysis. Recently an ELISA for C3NeF has been reported (Skattum, 2019). Both C3 and C5 Nephritic factors correlate with C3 consumption, while only C5 nephritic factors correlated with sC5b-9 levels (Corvillo et al., 2019).

Assessing cell surface expression and tissue deposition of complement proteins or fragments

The diagnosis of many autoimmune (or immune complex diseases) is based on the detection of immunoglobulins and complement deposition in various tissues. For immunohistochemical analysis, antibodies against C1q, C3b, C4b, C4d, and C5b-9 are available for frozen and in part also for paraffin fixed tissue. Positive staining identifies a direct impact of complement in the disease process, indicates disease activity and allows for the differentiation of the complement activation pathways involved. The presence of C3b suggests ongoing inflammation, while C3d deposits in the absence of C3b point to a non-active disease process. C4d has been accepted as biomarker of humoral renal graft rejection (Cohen et al., 2012).

In Paroxysmal Nocturnal Hemoglobinuria (PNH) increased susceptibility of red cell lysis is due to reduced expression of the complement inhibitors DAF (CD55) and CD59. These genetic deficiency of these non-transmembrane proteins affects their common GPI anchor. Flow cytometric quantification of DAF and CD59 is recommended for diagnostic testing (Ling and Murali, 2019).

Analysis of complement receptor 3 (CR3, CD11b/CD18) needs to be performed in cases of leukocyte adhesion deficiency (LAD) and of C5aR (CD88) if phagocyte response (e.g. chemotaxis) is impaired.

Standardization and quality control

The complex nature of complement testing and increasing clinical demand has been met in the last decade by efforts to improve the standardization among laboratories. Initiated by the IUIS/ICS Committee for the Standardization and Quality Assessment in Complement Measurements 14 rounds of external quality assessment since 2010 resulted in improvements in the consistency of testing across participating institutions, while extending the global reach of the efforts to more than 200 laboratories in 30 countries. World-wide trends of assay availability, usage and analytical performance are summarized based on the past years' experiences (Prohászka et al., 2016).

Future developments

As complement is a cascade of multiple pathways and multiple components, the value of being able to test across the pathways applying multiplex technology appears obvious. Using dried blood spot samples from newborns various complement deficiencies could be detected by multiplex immunoassays (Dezfouli et al., 2020). Taking another approach, the value of using mass

spectrometry to profile the complement system (Willems et al., 2020). This is considered to open a new avenue for the clinical immunology laboratory. However, its transfer to routine complement analysis still requires more efforts in standardization and quality assessment.

Introduction

Functional testing of the IFN- γ /IL-12 circuit is key for the diagnosis of Mendelian susceptibility to mycobacterial disease (MSMD, OMIM: 209950). MSMD belongs to the expanding group of disorders termed primary immunodeficiencies (PID), or, more recently, inborn errors of immunity (IEI), and is included in the group 6 named Defects in intrinsic and innate immunity. MSMD is characterized by a selective predisposition to intramacrophagic microorganisms in otherwise healthy individuals, particularly poorly virulent mycobacteria. This susceptibility is ascribed to inborn errors of immunity in components of the IFN- γ /IL12 circuit (Bustamante et al., 2014; Casanova and Abel, 2002). In a normal anti-mycobacterial response, after bacilli/us phagocytosis, antigen-presenting cells (APC) are activated and produce tumor necrosis factor (TNF)- α , interferon-stimulated gene (ISG) 15, interleukin (IL)-12p70, and IL-23, among other cytokines. These cytokines, together with antigen presentation to T helper (Th) cells, induces differentiation into Th1 cells and IFN- γ production. This activation process creates a positive loop between the T cell and the APC, which enhances the former's microbicidal capacity of the APC through increase of receptor-mediated phagocytosis, phago-lysosomal fusion and oxygen reactive species' (ROS) and nitride oxide production (Bogunovic et al., 2012; Cottle, 2011; D'Cunha et al., 1996; Ramirez-Alejo and Santos-Argumedo, 2014; Torrado and Cooper, 2013).

IL-12p70 is a heterodimer composed of a p40 subunit (in common with IL-23) and a p35 subunit, which bind IL-12R β 1 and IL-12R β 2, respectively, activating Th1 cells, gamma-delta T cells, NK and NKT cells, mucosal associated invariant T cells (MAIT cells) and innate lymphoid cells type 1 and type 2 (Zundler and Neurath, 2015). The Janus-associated kinase 2 (JAK2) and the tyrosine kinase 2 (TYK2) interact with the IL-12R β 1 and IL-12R β 2 subunits respectively, and mediated IL-12 receptor signaling, leading to Signal transducer and activator of transcription 4 (STAT4) phosphorylation. STAT4 then dimerizes and translocate as homodimers to the nucleus promoting IFN- γ production (Watford et al., 2004). IFN- γ response in APCs, especially in macrophages, is mediated

by its binding to IFN- γ receptor (IFN- γ R) 1 and IFN- γ R2. Signaling by the IFN- γ R is mediated by JAK1 and JAK2 and induces STAT1 phosphorylation at tyrosine 701, dimerization, and translocation of STAT-1 homodimers γ -activated factor (the gamma-interferon activated factor, GAF) to the nucleus. In the nucleus, GAF binds to gamma-interferon-activated sites (GAS) at ISGs, promoting their expression (Majoros et al., 2017; Stark, 2007).

MSMD is caused by monogenic defects in different molecules of this circuit (Fig. 1), which impair the production of, or the response to, IFN- γ , thereby disrupting protective immunity to mycobacterial infection. Although the first clinical description of MSMD was published in 1951 (Mimouni, 1951), it was not until 1996 that the first genetic etiology of MSMD, autosomal recessive (AR) IFN- γ R1 deficiency, was described in an infant with fatal BCG infection (Jouanguy et al., 1996; Newport et al., 1996). Until date, mutations in 18 genes have been found to cause isolated or syndromic MSMD (Fig. 1). These genes are involved in IFN- γ production (*IL12RB1* (de Beaucoudrey et al., 2010; Feinberg et al., 2004; van de Vosse et al., 2013), *IL12B* (Altare et al., 1998; Prando et al., 2013a), *IL12RB2* (Martínez-Barricarte et al., 2018) *IL23R* (Martínez-Barricarte et al., 2018) *ISG15* (Bogunovic et al., 2012; Zhang et al., 2015), *SPPL2A* (Kong et al., 2018; Rosain et al., 2019), *TYK2* (Kerner et al., 2019b; Kreins et al., 2015) and *RORC* (Okada et al., 2015)), cellular responses to IFN- γ (*IFNGR1* (Dorman et al., 2004; Feinberg et al., 2004; Jouanguy et al., 1996; Jouanguy et al., 1999, 2000; Sologuren et al., 2011), *IFNGR2* (Moncada-Velez et al., 2013; Rosenzweig et al., 2004b), *STAT1* (Chapgier et al., 2006a; Dupuis, 2001; Hirata et al., 2013) *JAK1* (Eletto et al., 2016) and *CYBB* (Bustamante et al., 2006, 2011a,b)) or both (*NEMO* (Bustamante et al., 2011b) and *IRF8* (Hambleton et al., 2011)). *NEMO* defects are not included in the group of MSMD disorders within the IUIS classification, but considered MSMD-causing by the group of Dr. Jean Laurent Casanova and Dr. Jacinta Bustamante, leaders in the field. Besides, *IFNG* (Kerner et al., 2020) and *TBK21* (Yang et al., 2020) have been included as two

Fig. 1 Summary of molecules involved in IFN- γ -mediated immunity. Molecules represented with **bold characters** are known to be cause of MSMD. Genes causing non-syndromic forms are displayed in **black**, genes causing both syndromic and non-syndromic forms in **purple** and genes causing only syndromic forms in **green**. Recognition and phagocytosis of the bacilli by antigen-presenting cells (APC) and macrophages, induces their activation and the production of an array of cytokines and chemokines, particularly tumor necrosis factor (TNF)- α , interferon-stimulated gene (ISG) 15, interleukin (IL)-12p70, and IL-23, which induce IFN- γ production by T, NK, and NKT cells. IL-12p40 (encoded by the *IL12B* gene) is common to IL-12p70 and IL-23. The IL-12R β 1 molecule is shared by both the IL-12 and IL-23 receptor heterodimers, whereas IL-12R β 2 and IL-23R are unique to the IL-12 and IL-23 receptors respectively. Tyk2 is a tyrosine kinase involved in IL-12R- and IL-23R-mediated signaling. ISG15 is secreted by many cell types, including myeloid cells and neutrophils, and it acts as a very potent IFN- γ -inducing cytokine in lymphocytes. *ISG15* also encodes an intracellular interferon-induced ubiquitin-like protein that acts as a negative regulator of IFN- α/β , resulting in enhanced IFN- α/β immunity. The *RORC* gene encodes two protein isoforms that act as transcription factors: the nuclear orphan receptor γ (ROR γ) is ubiquitously expressed, whereas the expression of ROR γ T is restricted to leukocytes. IFN- γ binding to the IFN- γ receptor, an heterodimer of IFN- γ R1 and IFN- γ R2, leads to activation of the tyrosine kinases Jak1 and Jak2, and to serine and tyrosine phosphorylation of the signal transducer and activator of transcription 1 (STAT1). Phosphorylated STAT1 forms a homodimer termed IFN-gamma-activated factor (GAF), which migrates into the nucleus and binds to the IFN gamma activated sequence (GAS) to drive the expression of the target genes. Interferon regulatory factor 8 (IRF8), is a transcription factor induced by IFN- γ , expressed in macrophages and dendritic cells. IRF8 binds to IFN-stimulated response elements (ISRE) and regulate the expression of many genes. *SPPL2A* encodes the signal peptide peptidase-like 2 A (SPPL2a), a protease with multiple substrates. A binding site for IRF8 has been identified in the Sppl2a promoter in mouse macrophages. *NEMO* encodes the Nuclear factor-kappa B (NF- κ B) essential modulator, which mediates signaling in the NF- κ B pathway, required, among other signaling pathways, for TNF receptor- and CD40L-mediated activation. gp91^{phox}, encoded by *CYBB*, is a major component of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (PHOX) complex, required for effective intracellular killing of microorganisms.

new causes of MSMD in 2021 (Tangye et al., 2021). Besides ZNFX1 deficiency has been reported associated with intermittent monocytosis and mycobacterial disease (Le Voyer et al., 2021).

Incidence for MSMD is described to be 1/50,000 worldwide (Rosain et al., 2019). Depending on the impact of the mutation (null or hypomorphic, resulting in complete or partial deficiency), the inheritance of the disease, the expression of the mutant allele (absent or detectable), or the mechanism responsible for the impaired function of the mutated protein, at least 30 different genetic etiologies of MSMD have been identified so far (Bustamante, 2020; Bustamante et al., 2014; Rosain et al., 2019). IL-12R β 1 deficiency and autosomal dominant (AD) partial IFN- γ R1 deficiency are the most common defects (Bustamante, 2020; Bustamante et al., 2014; Filipe-Santos et al., 2006a; Kerner et al., 2019a; Rosain et al., 2019). Patients with syndromic MSMD, mainly with mutations in *ISG15* (Bogunovic et al., 2012; Zhang et al., 2015), *RORC* (Okada et al., 2015), and *JAK1* (Eletto et al., 2016), manifest a more complex clinical phenotype, with a predisposition to other microorganisms or to other manifestations. In addition, mutations in *STAT1* (Chapgier et al., 2006b), *IRF8* (Hambleton et al., 2011), and *TYK2* (Kerner et al., 2019b; Kreins et al., 2015) can cause isolated or syndromic MSMD depending of the pattern of inheritance and the functional impact of the mutation. With so many forms, the clinical boundaries of MSMD, particularly of some of the less frequent etiologies, are not fully defined, and the genetic etiology remains unknown in about half of the patients.

Clinical spectrum of patients with defects of the IL-12/IFN- γ circuit

Mycobacteria

MSMD is usually characterized by vulnerability to poorly virulent mycobacteria, such as bacillus Calmette-Guérin (BCG) vaccines and environmental mycobacteria (EM), in otherwise healthy individuals, which tend to be considered the warning signs of this form of IEI. Also, infection by the more virulent *M. tuberculosis* has been documented in some patients, particularly in deficiencies of IL-12R β 1 (Boisson-Dupuis et al., 2011, 2015; Bustamante et al., 2014), IFN- γ R1 (Bustamante et al., 2014; Dorman et al., 2004), *STAT1* (Bustamante et al., 2014; Chapgier et al., 2006a), or IL-12p40 (Fieschi, 2004; Prando et al., 2013a).

Patients can present with a wide range of clinical manifestations of mycobacterial disease, from local BCGitis to disseminated, invasive and lethal infections. Disease onset is usually in childhood, but diagnosis in adolescence and adulthood have been reported. Usually, the most severe forms (AR complete IFN- γ R1 or IFN- γ R2 deficiency) show an early onset, and infections use to be persistent and life-threatening in spite of anti-mycobacterial treatment. On the other hand, other less severe forms of MSMD (partial -AR or AD- deficiencies of IFN- γ R1 and IFN- γ R2 or deficiencies of the IL-12/IL-23 receptors) can have a late onset, they can improve with age, and the infections can be relatively circumscribed (Arend, 2001; Boudjemaa et al., 2016; Bustamante et al., 2014; Hirata et al., 2013; Jirapongsananuruk et al., 2012; Obinata et al., 2013; Rosain et al., 2019; Sasaki et al., 2002; Shamriz et al., 2013; Tsumura et al., 2012a). Patients that survive to a mycobacterial disease, may suffer from another mycobacterial infection or remain healthy; likewise, mycobacterial infections may or may not recur.

Other intramacrophagic bacterial and fungal infections

Besides the increased susceptibility to mycobacteria, patients with MSMD may also be prone to infections by other intramacrophagic microorganisms: about half of the patients suffer from salmonellosis (frequently extra gastrointestinal), particularly non typhoidal, and more rarely typhoidal; rare cases of infections caused by intramacrophagic fungi (histoplasmosis, coccidioidomycosis, paracoccidioidomycosis), parasites (Leishmaniasis, Toxoplasmosis) and bacteria (listeriosis, nocardiosis, klebsiellosis) have been also reported.

Candida

In addition, since IL-12R β 1 is also part of the IL-23 receptor and IL-12p40 is also a subunit of IL-23, required for expansion of Th17 and Th1* cells (Martínez-Barricarte et al., 2018), patients with IL-12R β 1 and IL-12p40 deficiencies are prone to mild forms of chronic mucocutaneous candidiasis (CMC) (Ouederni et al., 2014; Prando et al., 2013a). Patients with *RORC* deficiency also present with CMC (Okada et al., 2015).

Virus

Complete deficiencies of IFN- γ R1 and IFN- γ R2 can rarely predispose to viral disease, particularly but not exclusively by herpes viruses (Bustamante et al., 2014). Autosomic recessive forms of *IRF8*, *STAT1* LOF and *TYK2* deficiency, not included in the MSMD classification, as well as *JAK1* deficiencies also confer susceptibility to severe viral infections since their loss of function interferes with type I IFN signaling. This is why they are included in the "Predisposition to severe viral infection" subgroup within Defects in intrinsic and innate immunity in IUIS classification. They can particularly combine severe forms of mycobacterial and viral disease (Boisson-Dupuis et al., 2012). On the other hand, patients usually have a normal resistance to other microorganisms.

Clinical penetrance of MSMD may be incomplete, and it usually correlates with the extent of IFN- γ -mediated immunity. Complete AR IFN- γ R1 and IFN- γ R2 deficiencies are fully penetrant and they are always lethal in the absence of hematopoietic stem cell transplantation (HSCT). By contrast, clinical penetrance is partial, and even very low, in patients with deficiencies of the

IL-12 and/or IL-23 receptors. Only 50–70% of adults with IL-12R β 1 deficiency, who have abolished IL-12- and IL-23 mediated responses, are symptomatic by the age of 40 years (Bustamante et al., 2014; de Beaucoudrey et al., 2010; Rosain et al., 2019). However, the clinical penetrance of IL-12R β 2 deficiency, which do not affect IL-23-mediated responses, as well as IL-23R and of partial AR Tyk2 deficiencies, which show normal IL-12-mediated responses, is very low (about 0.5%), and most patients remain asymptomatic in adulthood (Kerner et al., 2019b; Martínez-Barricarte et al., 2018; Rosain et al., 2019). Therefore, some of the genetic etiologies of MSMD do not segregate as a bona fide mendelian trait.

Who should be tested for defects of the IL-12/IFN- γ circuit? Differential

Warning signs for MSMD

Children or adults who develop recurrent or severe/disseminated mycobacterial infectious disease caused by BCG, EM, *M. tuberculosis*, or *Salmonella*, alone or in combination with other intramacrophagic pathogens or viruses, and for whom no other hemato-immunological conditions nor immunosuppressants can be demonstrated, should be tested for defects on the IL12/IFN- γ circuit. Specific warning signs for MSMD are summarized in Table 1. Routine hematological and immunological analysis for a suspected immunodeficiency (including) (1) T cell maturation, (2) proliferation after mitogen stimulation and (3) oxidative burst reactions, tend to be normal in patients with MSMD, although monocytopenia and DC deficiency, may be present in patients with IRF8 and SPPL2a deficiency.

Differential: Other IEI with similar infectious susceptibility

It is important to consider that MSMD is not the only IEI predisposing to mycobacterial disease (Boisson-Dupuis et al., 2015; Picard et al., 2018); indeed, other IEI can manifest with the above mentioned infections, but they also tend to manifest other infectious and immunological phenotypes (Boisson-Dupuis et al., 2015). These other mycobacterial infection-predisposing IEI to be discarded include: (i) patients with defects in the number and/or function of T-cells (severe combined immunodeficiencies and combined immunodeficiencies), (ii) chronic granulomatous disease (particularly susceptible to BCG and *M. tuberculosis*), and (iii) GATA2

Table 1 Warning signs for MSMD and other conditions to be discarded.

Age	Usually in childhood, also in adolescence and adulthood
Patient history	Otherwise healthy individuals
Clinical signs	Invasive or recurrent infections by: Mycobacteria: • BCG infection (<i>Mycobacterium bovis</i> vaccine strain) • Environmental mycobacteria (<i>M. chelonae</i>, <i>M. fortuitum</i>, <i>M. mageritense</i>, <i>M. peregrinum</i>, <i>M. smegmatis</i>, <i>M. scrofulaceum</i>...) • <i>Mycobacterium tuberculosis</i> Intramacrophagic bacteria (alone or in combination with mycobacteria): • <i>Salmonella</i> spp. • <i>Listeria monocytogenes</i>/<i>Nocardia</i> spp./<i>Klebsiella</i> spp. Fungi (alone or in combination with mycobacteria): • <i>Candida</i> spp. • <i>Histoplasma capsulatum</i>/<i>Paracoccidioides brasiliensis</i>/<i>Coccidioides</i> spp. Parasites (alone or in combination with mycobacteria, rare): • <i>Leishmania</i> spp. • <i>Toxoplasma gondii</i> Virus (in combination with mycobacteria, rare): • Cytomegalovirus, human herpes virus 8, parainfluenza virus type 3, respiratory syncytial virus and varicella zoster virus.
Other signs	Family history of invasive or recurrent mycobacterial infection Undetectable or very low IFN- γ production in IFN- γ release Tests (i. e. QuantiFERON-TB Gold In-Tube)
Differential	Other IEI: • T cell defects (severe combined immunodeficiency and combined immunodeficiency) • Chronic granulomatous disease • GATA2 deficiency Acquired immunodeficiencies: • Immunosuppressive drugs exposure (including biologic drugs to molecules in the pathway) • Stem cell transplantation • Malignancy • Human immunodeficiency virus infection • Congenital lung defects • Bronchiectasis, chronic obstructive pulmonary disease Presence of neutralizing anti-IFN- γ autoantibodies

BCG, bacille Calmette-Guérin.

deficiency, predisposing to disseminated EM infections, and less frequently to tuberculosis, which may be the first clinical presentation even in otherwise healthy adults, although they can also occur during childhood. However, GATA2 patients have a broader clinical spectra, including viral infections, particularly warts, hematological disorders (myelodysplastic syndrome/leukemia), pulmonary alveolar proteinosis, and other non-immunological anomalies (Cohen et al., 2016; Donadieu et al., 2018; Sologuren et al., 2018). Patients with GATA2 have severe circulating monocytopenia (78% of patients), and B (86% of patients) and NK (82% of patients) (Donadieu et al., 2018; Hsu et al., 2011; Spinner et al., 2014) lymphopenias. Characteristically, patients with GATA2 deficiency show specific loss of the CD56^{bright} NK subset (Mace et al., 2013). Besides, patients suffering severe combined immunodeficiencies, combined immunodeficiencies, chronic granulomatous diseases and X-linked NF- κ B deficiency anhidrotic ectodermal dysplasia with immunodeficiency (XR-EDA-ID) syndrome are susceptible to a wide range of pathogens (pyogenic bacteria, virus) including mycobacteria (Bustamante et al., 2014; Orange et al., 2002, 2004; Picard and Casanova, 2004).

Differential: acquired immunodeficiencies and other conditions with similar infectious susceptibility.

In addition, acquired immunodeficiencies predisposing to mycobacterial diseases must also be excluded (Boisson-Dupuis et al., 2015): immunosuppressive drugs exposure (Brode et al., 2015; Lake et al., 2016), stem cell transplantation, malignancy (Arlotta et al., 2014; Kraut, 2003; Netea et al., 2008; Thaker et al., 2001), biologicals, particularly those against TNF- α -mediated immunity, and JAK inhibitors (Hirai et al., 2020) or human immunodeficiency virus infection (Boisson-Dupuis et al., 2015; Lake et al., 2016; Orme and Ordway, 2014) (HIV; BCG vaccination is contraindicated in HIV-infected individuals). Environmental mycobacteria and *M. tuberculosis* infections are increasingly being reported in patients with congenital lung defects such as primary ciliary dyskinesia, pulmonary alveolar proteinosis, and cystic fibrosis and other pulmonary complications such as bronchiectasis, chronic obstructive pulmonary disease.

Finally, patients that have neutralizing anti-IFN- γ autoantibodies can develop MSMD-like clinical manifestations, and they are included in group X of the IUIS classification, which is called phenocopies of inborn errors of immunity (Hanitsch et al., 2015; Kampmann et al., 2005; Lee et al., 2013; Picard et al., 2018; Tangye et al., 2020; Wu et al., 2018). Neutralizing anti-IFN- γ autoantibodies have been mostly described in females with Southeast descent (Hong et al., 2019), and are associated with HLA-DR*15:02/16:02 and HLA-DQ*05:01/05:020020 (Ku et al., 2016). Treatment with rituximab has been shown to be efficient for the treatment of these patients (Browne et al., 2012b). The description of the methods that can be used to identify the presence of neutralizing anti-IFN- γ autoantibodies is described below.

IL-12/IFN- γ circuit functional testing studies

IFN- γ circulating levels

Quantitation of IFN- γ levels in plasma by enzyme-linked immunosorbent assay (ELISA) is a fast and easy technique for detection of IFN- γ R deficiencies (Bustamante et al., 2014; Fieschi et al., 2001; Martínez-Barricarte et al., 2014). Patients with complete IFN- γ R deficiencies have increased levels of IFN- γ in plasma (150–1700 pg/mL) (Fieschi et al., 2001; Martínez-Barricarte et al., 2014); patients with partial deficiency of IFN- γ R present detectable levels of IFN- γ (51–222 pg/mL) (Sologuren et al., 2011) while it is undetectable in other MSMD forms and in healthy controls (Fieschi et al., 2001; Martínez-Barricarte et al., 2014; Moncada-Velez et al., 2013; Olbrich et al., 2015; Rottman et al., 2008; Sologuren et al., 2011). Of note, in a case series of partial IFN- γ R1 deficiency a patient with acute mycobacterial disease had specially high IFN- γ levels (925 pg/mL). Thus, the infectious state of the patient needs to be considered, as circulating IFN- γ plasma levels may vary in acute infection compared with the convalescent phase (Sologuren et al., 2011), being a confounding factor for differential diagnosis between complete and partial AR IFN- γ R1 or IFN- γ R2 deficiency in rare cases (Martínez-Barricarte et al., 2014; Moncada-Velez et al., 2013; Sologuren et al., 2011). Therefore, if possible, circulating IFN- γ levels should be measured at least 1 month after acute infection resolution. In any case, no IFN- γ is usually detected in the plasma of healthy individuals (Fieschi et al., 2001; Martínez-Barricarte et al., 2014). At a technical level, plasma samples need to be diluted at least 1:2 to avoid interference of other proteins such as fibrinogen. The assay may be performed in serum samples, but proper controls should be performed. Serum and plasma levels of cytokines are not exchangeable, since differences in the matrix affect cytokine detection (Esteve-Sole et al., 2021; Rosenberg-Hasson et al., 2014).

Cytometric evaluation of receptors' expression

IFN- γ R1/IFN- γ R2 expression

IFN- γ receptor detection by flow cytometry is a fast technique for the detection of complete forms of AR IFN- γ R1 and AR IFN- γ R2 deficiency with absent protein expression in the membrane of monocytes. Approximately an 80% of complete AR IFN- γ R1 deficiencies can be detected (Bustamante et al., 2014; de Beaucoudrey et al., 2010; Ehlayel et al., 2008; Esteve-Sole et al., 2018b; Jouanguy et al., 1999, 2000; Kong et al., 2013; Moncada-Velez et al., 2013; Olbrich et al., 2015; Sologuren et al., 2011). It can be performed both in WB and in PBMCs. In partial AR IFN- γ R1 defects, there is usually a weak expression of the receptor (Bustamante et al., 2014; Sologuren et al., 2011); contrarily, high levels of protein expression have been reported in partial AD IFN- γ R1 deficiency due to mutations in the recycling motif (Bustamante et al., 2014; Jouanguy et al., 1999). Detection of IFN- γ receptors could be affected by the antibody used: for example, IFN- γ R1 in cells of patients with the p.C77Y complete AR IFN- γ R1 defect would be identified with the gR99 clone and not with the gR38 clone (Jouanguy et al., 2000). Similarly, there are some AR IFN- γ R2 defects with protein expression, and partial AD/AR defects show low but detectable IFN- γ R2 in the membrane of monocytes (Bustamante

et al., 2014; Kong et al., 2013; Moncada-Velez et al., 2013). The currently available antibodies for the evaluation of IFN- γ R2 expression are not optimal. In patients with suspected MSMD and normal receptor detection other techniques that evaluate cellular responses to IFN- γ should be performed.

IFN- γ binding studies

As discussed above, in some IFN- γ receptor 1 deficiencies there is protein expression in the membrane. Some of these mutations lead to poor IFN- γ binding. Detection of IFN- γ binding may be performed with radiolabeled 125 IFN- γ or by flow cytometry (Jouanguy et al., 1999; Rosenzweig et al., 2004b; Sologuren et al., 2011). For flow cytometry, PBMCs are first incubated with different concentrations of hrIFN- γ for 30 min, and then washed and incubated for 20 min with an anti-IFN- γ antibody and acquired with a flow cytometer (Rosenzweig et al., 2004b; Sologuren et al., 2011). With this technique, membrane-expressing IFN- γ R1 defects can be easily detected. IFN- γ -binding assays with flow cytometry do not yield consistent results with Epstein-Barr virus-transformed B cells (EBV-B cells), and when using PBMCs, gating on monocytes is required (Sologuren et al., 2011). Some MSMD etiologies (AD IFN- γ R1 deficiency) will escape this detection (Jouanguy et al., 1999). To our knowledge, only four patients and three healthy controls have been evaluated so far (Rosenzweig et al., 2004b; Sologuren et al., 2011).

IL-12R β 1 expression

IL-12R β 1 deficiency is the most common genetic form of MSMD (Bustamante, 2020; Bustamante et al., 2014), with more than 200 cases described (Bustamante, 2020). IL-12R β 1 expression detection with flow cytometry is performed in PBMCs after 72 h of stimulation with PHA (de Beaucoudrey et al., 2010) (Fig. 2). Cytometric determination of IL-12R β 1 expression is a powerful and easy-to-perform technique that allows the detection of more than 99% of the described mutations (de Beaucoudrey et al., 2010; Ehlayel et al., 2008; Esteve-Sole et al., 2018b), excluding a large deletion (700 + 362_1619-944del) in IL12RB1 (Fieschi, 2004) and an N-terminal signal peptide stop-gain homozygous mutation (de Souza et al., 2017).

Cytometric detection of phosphorylated STAT molecules

STAT proteins bind to activated extracellular receptors, phosphorylate, dimerize, and translocate to the nucleus to bind to specific DNA regions and activate gene transcription (Casanova et al., 2012; Majoros et al., 2017; Stark, 2007). The two most relevant STAT molecules implicated in the IFN- γ circuit are STAT1 and STAT4 (Qu et al., 2011). Flow cytometric determination of STAT1 phosphorylation can be performed both in whole blood and in isolated PBMCs, while STAT4 phosphorylation in response to IL-12p70 needs to be performed in activated lymphocytes. The general protocols includes: (1) stimulation at different cytokine concentrations for 15–30 min, (2) fixation and permeabilization with special buffers for phosphorylation assays (3) staining with anti-phosphorylated STAT antibodies in conjunction with extracellular antibodies of choice and (4) acquisition with a flow cytometer (Chapgier et al., 2006a; Fieschi, 2004; Hirata et al., 2013; Sampaio et al., 2012; Sologuren et al., 2011). It should be stressed that when working with anti-STAT antibodies, proper negative controls are mandatory. Of note, STAT4 phosphorylation evaluation is limited by the lack of a proper antibody to detect total STAT4.

Fig. 2 Step-by-step proposed diagnostic algorithm for suspected defects of the IL-12/IFN- γ circuit. *SCID*, severe combined immunodeficiency; *CID*, combined immunodeficiency; *CGD*, chronic granulomatous; *NGS*, next generation sequencing; *IEI*, inborn errors of immunity; *WES*, whole exome sequencing; *WGS*, whole genome sequencing. * Especially in adult female patients of Southeast Asian descent. ** For non-reported variants. Guidelines for functional validation of single variants are depicted in Casanova et al. in 2014 (Casanova et al., 2014).

STAT1 phosphorylation

STAT1 phosphorylation has been shown useful for detection of complete and partial defects of STAT1 and IFN- γ receptors. Complete defects in IFNGR1 and IFNGR2 genes lead to abolished STAT1 phosphorylation in response to hrIFN- γ while a normal response to hrIFN- α is observed (Kong et al., 2010b, 2013; Rosenzweig et al., 2004a,b; Sologuren et al., 2011). Partial defects lead to impaired, but not abolished, STAT1 phosphorylation after hrIFN- γ stimulation in a dose-dependent manner; this altered response is normalized after high dose stimulation (de Paus et al., 2011; Janssen et al., 2002; Kong et al., 2010b, 2013; Moncada-Velez et al., 2013; Okada et al., 2007; Sologuren et al., 2011; Storgaard et al., 2006). Concentration of IFN- γ or hrIFN- α stimulation for STAT1 phosphorylation assays range from 10 to 10^5 IU/mL, being 10^3 IU/mL and 10^5 IU/mL the most common concentrations used (Chapgier et al., 2006a; Dupuis, 2001; Jouanguy et al., 1999; Kong et al., 2010a,b; Sologuren et al., 2011; Takeda et al., 2014; Tsumura et al., 2012b). STAT1 phosphorylation after low-dose IFN- γ stimulation will detect almost all IFN- γ receptor defects and approximately 70% of STAT1 defects.

Impaired or abolished phosphorylation to both hrIFN- γ and hrIFN- α suggests a STAT1 deficiency but normal phosphorylation does not exclude it. Although phosphorylation is the first step for STAT1 function, mutations on other STAT1 domains implicated in later events can impair STAT1 function with normal phosphorylation. For example, AD STAT1 LOF mutations in the tail segment domain or SH2 domain (except the p.M654K mutation exception (Sampaio et al., 2012)) lead to impaired STAT1 phosphorylation in response to hrIFN- γ but not hrIFN- α (Dupuis, 2001; Hirata et al., 2013; Tsumura et al., 2012b). In contrast, mutations in the DNA-binding domain can lead to both normal (E320Q and p.Q463H mutation (Chapgier et al., 2006a)) and altered (p.E157K and p.G250E mutation (Kagawa et al., 2017)) STAT1 phosphorylation. Furthermore, it has been recently reported that patients with AD STAT1 gain of function mutations, who usually develop chronic mucocutaneous candidiasis, but also other infectious phenotype and clinical manifestations, can also develop mycobacterial infectious disease (Kagawa et al., 2017; Toubiana et al., 2016).

STAT4 phosphorylation

STAT4 signals downstream the IL-12 receptor. After IL-12 binding to the IL-12 receptor, IL-12R β 1 binds TYK2 and IL-12R β 2 associates with JAK2, initiating trans-phosphorylation of the receptors. This creates a docking site for STAT4, where it is phosphorylated at tyrosine 693, dimerizes, and undergoes nuclear translocation where it binds to its target DNA sequences (Watford et al., 2004). For STAT4 phosphorylation cytometric assay PBMCs are stimulated for 72 h with phytohemagglutinin (PHA), cultured 48 h in the presence of IL-2 and then stimulated with hrIL-12p70; the whole assay takes approximately 1 week (Fieschi, 2004; Uzel et al., 2001). Abolished STAT4 phosphorylation in response to hrIL-12p70 has been observed both in IL-12R β 1-(Ehlayel et al., 2008; Fieschi, 2004) and TYK2-deficient patients (Kreins et al., 2015). Otherwise, STAT1 phosphorylation after IFN- α is normal in IL-12R β 1-deficient patients (Fieschi, 2004) and impaired in TYK2 deficient patients (Kreins et al., 2015). However, STAT4 phosphorylation results must be interpreted with caution due to the lack of a proper STAT4 antibody to assess total STAT4 expression by flow cytometry. For this reason, STAT4 is meant to help only in the diagnosis of other forms of MSMD.

Cytokine production evaluation

Evaluation of cytokine production, developed by Feinberg et al (Feinberg et al., 2004), is the gold standard for study of IL-12/IFN- γ circuit. This assay is based on the measurement of IL-12p40, IL-12p70 and IFN- γ after whole blood or, less frequently, peripheral blood mononuclear cells (PBMCs) stimulation. Stimulation conditions comprise incubation with live BCG at a multiplicity of infection of 20 BCG/leukocyte with or without hrIL-12p70 (20 ng/mL), or hr-IFN- γ (5000 IU/mL) co-stimulation for 18 h (for IL-12 measurement) or 48 h (for IFN- γ and IL-12 measurements) (Esteve-Sole et al., 2018b; Feinberg et al., 2004). Detection of the cytokines produced may be performed with ELISA or multiplex assays by means of flow cytometry (Luminex Technology (Luminex, Austin, TX, USA) or cytometric bead array systems) (Feinberg et al., 2004; Olbrich et al., 2015; Sologuren et al., 2011). However, absolute values obtained by the different techniques are not directly comparable, hampering the definition of cut-off values.

Although powerful, this technique has several limitations: (1) the intrinsic variability observed yet in healthy controls, that hampers interpretation of results, especially of partial defects (de Beaucoudrey et al., 2010; Esteve-Sole et al., 2018b; Feinberg et al., 2004). Because of that, there are not cut-off values described. To overcome this limitation, evaluation of an in-house healthy controls' cohort may help to define normal ranges of cytokine production. In our experience (Esteve-Sole et al., 2018a; Esteve-Solé et al., 2018), the lower 10th percentile of the control cohort may define a weak response, (2) if fresh whole blood is used, it should be performed during the first 48 h after extraction (de Beaucoudrey et al., 2010), and (3) the use of BCG stimulation can be limiting in diagnostic laboratories following ISO 15189 regulations. In an attempt to solve limitations, different strategies have been developed, including the performance of the test in cryopreserved cells to eliminate time-from-extraction limitation and the use of phytohemagglutinin and lipopolysaccharide as stimuli to avoid the use of BCG; the stimulation condition will then be phytohemagglutinin (PHA; 1%) in the presence or not of IL-12p70 (Dorman and Holland, 1998) or LPS (from *Salmonella minnesota*; 100 ng/mL) with and without hrIFN- γ (10^2 , 10^3 and 10^4 IU/mL) (Sologuren et al., 2011) costimulation.

This assay help to distinguish between IFN- γ response defects and IFN- γ production defects. Complete forms of IFN- γ R1, IFN- γ R2, IL-12RB1 or IL-12p40 can be detected with this approach. IFN- γ production defects are characterized by the absence or low production of IFN- γ after BCG stimulation (4–726 pg/mL for IL12RB1 defects (de Beaucoudrey et al., 2010; Feinberg et al., 2004) and below 100 pg/mL for IL12p40 defects (Feinberg et al., 2004; Prando et al., 2013b)). If there is no recovery of IFN- γ after hrIL-12p70 co-stimulation, IL-12R β 1 deficiency should be studied first (de Beaucoudrey et al., 2010), followed by ISG15 or TYK2

deficiencies (Bogunovic et al., 2012; Kreins et al., 2015). On the other hand, in patients with IL-12p40 deficiency decreased levels of IFN- γ in response to BCG stimulation can be rescued, at least partially, with exogenous hrIL-12p70. IL12p70 secretion is normal in patients with IL-12R β 1 deficiency and abolished in patients with IL-12p40 deficiency. Patients with complete deficiency of IFN- γ R1 or IFN- γ R2 showed normal production of IFN- γ in response to BCG in the presence or absence of IL-12p70. However, there is no response to hrIFN- γ in terms of IL-12 production (Dorman et al., 2004; Dorman and Holland, 1998; Feinberg et al., 2004; Holland et al., 1998; Kong et al., 2013; Noordzij et al., 2007; Prando et al., 2010; Rosenzweig et al., 2004a; Vogt et al., 2005). On the other hand, in partial IFN- γ response defects (partial AR IFN- γ R1/IFN- γ R2 and partial AD STAT1 LOF deficiency), the response to hrIFN- γ is impaired in a dose-dependent manner, but not abolished (Allende et al., 2001; Chapgier et al., 2006a; Dorman et al., 2004; Hirata et al., 2013; Janssen et al., 2002; Jouanguy et al., 1997, 2000; Kilic et al., 2012; Okada et al., 2007; Sologuren et al., 2011; Takeda et al., 2014; Tsumura et al., 2012b).

Some genetic etiologies of MSMD, such as gp91^{phox} or AD IRF8 deficiency, will show normal responses to this stimulation (Bustamante et al., 2011a; Hambleton et al., 2011; Puel et al., 2006). Nevertheless, in nuclear factor-kappa B essential modulator (NEMO)-deficient patients, IL-12 production is normal after BCG stimulation but impaired after PBMC stimulation with PHA or anti-CD3 antibodies (Bustamante et al., 2006; Filipe-Santos et al., 2006b). ROR γ C deficient patients resemble patients with IL-12RB1 deficiency, with little IFN- γ production after BCG stimulation which is not rescued after IL-12p70 stimulation (Okada et al., 2015). This has not been assayed for other new MSMD etiologies such as SPPL2A, IL-23R and IL-12RB2 deficiency.

Detection of neutralizing anti-IFN- γ autoantibodies

Since 2004, first reports of the existence of neutralizing autoantibodies against IFN- γ in patients with disseminated mycobacterial diseases have been published (Boisson-Dupuis et al., 2015; Doffinger et al., 2004; Hong et al., 2019; Liew et al., 2019; Phoompoung et al., 2017). This condition is not considered as MSMD but it is included here because it is classified as a phenocopy defects on the IL-12/IFN- γ circuit and should be included in the differential diagnosis of MSMD. This disorder affects predominantly, but not exclusively, to adults of Asian descent (Hong et al., 2019; Liew et al., 2019; Phoompoung et al., 2017). Most patients suffer from infections by environmental mycobacteria, but *M. tuberculosis* have also reported (Boisson-Dupuis et al., 2015). This condition is frequently associated with infections by other intramacrophagic microorganisms such as *Salmonella*, *Cryptococcus neoformans*, *Histoplasma capsulatum*, or *Penicillium marneffei*.

Presence and level of autoantibodies against IFN- γ can be assessed by an ELISA system against anti-IFN- γ -antibodies with different serum dilutions and by observing IFN- γ level recovery after the addition of exogenous IFN- γ to patient serum (Browne et al., 2012a; Chi et al., 2013; Hanitsch et al., 2015; Kampmann et al., 2005; Lee et al., 2013; Patel et al., 2005). In addition, it has been recently shown that undetectable or very low IFN- γ production in QuantiFERON-TB Gold In-tube is a warning sign for the presence of anti-IFN- γ antibodies (Wu et al., 2018). Only the presence of neutralizing autoantibodies against IFN- γ explains the susceptibility to intramacrophagic microorganisms. IFN- γ response assays, such as STAT1 phosphorylation or cytokine production, in the presence of patients' sera must be performed to analyze the neutralizing activity of IFN- γ autoantibodies (Hanitsch et al., 2015; Hong et al., 2019; Koizumi et al., 2017; Lee et al., 2013; Shima et al., 2014).

Other tests for the evaluation of the IL12/IFN- γ circuit

Because samples of primary cells from patients are not infinitely available, some tests have been adapted to the use of patient-derived cell lines. Epstein Barr Virus (EBV)-B cells, herpes virus saimiri-transformed T cells (T-saimiri cells), and immortalized SV-40 fibroblasts are the most common cell lines used (de Paus et al., 2011; Doffinger et al., 2000; Jouanguy et al., 1999; Kong et al., 2010b; Kreins et al., 2015; Moncada-Velez et al., 2013; Sologuren et al., 2011). IFN- γ R1, IFN- γ R2 and IL12RB1 expression and STAT1 phosphorylation may be evaluated in patients' cell lines, as well as STAT1 phosphorylation. The group of tests described below requires a laboratory with experience in the field of MSMD and is usually performed in a research laboratory context. Some defects have specific associated immunological features, depicted in Table 2.

IFN- γ response specific tests

IFN- γ response may be thoroughly study with the evaluation of signal transduction and evaluating its effects. For example, expression of activation markers such as HLA-DR and CD64 after stimulation with different hrIFN- γ concentrations may be used to determine response to IFN- γ , both in primary cells and in transformed SV40-fibroblasts and EBV-B cells (Allende et al., 2001; Jouanguy et al., 1997; Kong et al., 2010b). At a molecular level, electrophoretic mobility shift assay (EMSA), or quantification of the translocation of STAT-1 homodimers to the nucleus and their binding to DNA by means of ELISA, are used to evaluate STAT1 binding to target DNA, revealing also a correct nuclear translocation. These technique may help to detect AD STAT1 LOF deficiencies where phosphorylation is present. In addition, it can also help to identify AD STAT1-GOF deficiency (Dupuis, 2001; Tsumura et al., 2012b). Similarly, it is possible to study induction of GAS in response to IFN- γ . Specifically, expression of CXCL9 and CXCL10, among others, or the activation of GAS elements by luciferase detection (Chapgier et al., 2006a; Kagawa et al., 2017; Kong et al., 2010a; Sampaio et al., 2012; Sologuren et al., 2011; Tsumura et al., 2012b), can help to determine the effect of specific mutations. These approaches are usually used in research rather than in healthcare practice.

Table 2 Associated immunological features in particular defects of the IL-12/IFN- γ circuit.

CYBB deficiency	Abolished respiratory burst in monocyte-derived macrophages in response to purified protein derivative (PPD) or BCG, and in EBV-B cells. However, this oxidative burst defect cannot be detected in a routine dihydrorhodamine test, since monocytes, neutrophils, and monocyte-derived dendritic cells have normal responses (Bustamante et al., 2011a; Conti et al., 2015).
Partial AD IRF8 deficiency and SPPL2A deficiency	Loss of CD11c ⁺ CD1c ⁺ blood dendritic cells and a defect of IFN- γ production by mycobacterium-specific Th1 ⁺ cells (Hambleton et al., 2011; Kong et al., 2018). Besides, in SPPL2A deficiency, there is an accumulation of a N-terminal fragment of CD74 in the cell membrane of SPPL2a deficient cells (Kong et al., 2018).
NEMO deficiency causing MSMD	Normal NEMO expression in monocytes and T cells. Functionally, there is a low production of IFN- γ , IL-12p40, IL-12p70 after PHA stimulation in a T cell/Monocytes co-culture system. Besides, they have a lower IL10 production after TNF- α stimulation (WB) (Bustamante et al., 2011b; Filipe-Santos et al., 2006b).
ROR γ T deficiency	Normal protein expression and nuclear localization, impaired DNA binding; barely detectable ILC3; mucosa associated innate cells (MAIT) and NKT cells, mild CD4 and CD8 lymphopenia, severe impairment in the production of IL-17A, IL-17F, and IL-22 after polyclonal stimulus, and normal IFN- γ secretion by naïve or memory CD4 ⁺ T cells but strongly impaired IFN- γ production by Th1 ⁺ cells, and $\gamma\delta$ T cells (Satoshi Okada et al., 2015).
IL-12p40 deficiency	Lower than normal frequency of CD3 ⁺ IL-17A ⁺ cells ex vivo. T cells were capable of IL17 production after IL-23 stimulation (Prando et al., 2013b).
IL-12/IL-23 signaling defects	<i>IL12RB1</i> , <i>IL12RB2</i> and <i>IL23R</i> genes have increased frequency of naïve CD4 and CD8 cells and reduced levels of memory Th1 and Th1 ⁺ (Martínez-Barricarte et al., 2018). In vivo differentiation of naïve T cells to Th1 is abolished in <i>IL12RB1</i> and <i>IL12RB2</i> deficiencies but normal in <i>IL23R</i> deficiency. IL-17 differentiation is affected in <i>IL12RB1</i> and <i>IL23R</i> deficient patients and normal in <i>IL12RB2</i> deficient patients (Martínez-Barricarte et al., 2018). <i>IL12RB1</i> deficient patients have diminished IL-17-producing T cells ex vivo T cells were incapable of IL17 production after IL-23 stimulation (de Beauclourey et al., 2010) and a reduced frequency of circulating memory Tfh and memory B cells, with the functional consequence of lower avidity of tetanus toxoid-specific serum antibodies (Schmitt et al., 2013).
TYK2 deficiency	Impaired response to IL-10 after LPS and TNF- α stimulation of PBMCs, with diminished IL-10R2 cell surface expression and impaired STAT3 phosphorylation and EMSA assay after IL-10 stimulation. Patients have normal IL17 ⁺ cells in PBMCs after PMA/Ionomycin stimulation; impaired IL17A and F production in naïve T cells. Besides, in HerpesVirus Simplex-transformed T cells, there are abolished response to IL-12p70 objectified by abolished STAT4 phosphorylation, GAS and IFN- γ production. Besides, abolished STAT1 phosphorylation in response to IFN- α is observed. There is an abolished IL-23 response (STAT3-p, IFN- γ production and STAT3 phosphorylation). STAT3 phosphorylation and EMSA after IL-6/IL-21/IL-27 stimulation is normal (Kerner et al., 2019b; Kreins et al., 2015).

Molecular testing for defects in the IL-12/IFN- γ circuit

Genetic confirmation of the diagnosis of MSMD is of outmost importance for treatment and genetic counseling. MSMD may be caused by deficiencies in a relatively high number of genes; because of that, Sanger sequencing is only recommended when the clinical presentations and functional tests clearly suggest a specific gene defect. Otherwise, next generation sequencing (NGS) should be the option of choice to reduce time-to-response and costs (Cordero et al., 2020; Meyts et al., 2016). For general healthcare practice, gene panels including all known genes to be causative of MSMD have a good cost-efficiency ratio, being a good option to detect somatic mutations; since gene panels may be sequenced at high coverage. However, almost half of the patients with clinical signs suggestive of MSMD do not show mutations in these genes (Bustamante, 2020; Bustamante et al., 2014; Rosain et al., 2019).

Because of the reduction in time and cost during the last years, whole exome sequencing (WES) or whole genome sequencing (WGS) are being more used to overcome this limitation. WGS may reveal mutations in non-coding regulatory regions that would be undetectable by WES, but WGS is more expensive and difficult to interpret than WES. In fact, an increasingly used approach for the evaluation of PID (including MSMD) is to start with a panel or semi-targeted panel using NGS and then perform functional tests to confirm the observed variants. These techniques allow to detect defects that may not be detected by conventional Sanger sequencing such as copy number variations (Rosain et al., 2018).

Functional validation of unknown genetic variants

Unknown variants in known disease-causing genes or new genes must be functionally confirmed to be deleterious. Recommended guidelines for considering single-patient mutations to be disease-causing have been reported (Casanova et al., 2014; Tangye et al., 2021) and different strategies are proposed in order to study the deleterious effects of specific mutations (Kagawa et al., 2017). Nowadays, advanced in silico prediction tools are available online to help to predict the effect of a variant in protein; however, these analyses are not sufficient to validate the deleterious effect of a variant. Protein expression and functionality should be studied in vitro. Transfection of different cell lines with wild-type or mutated genes may be useful for the evaluation of variants of interest to evaluate protein expression and function. Disease-causing variants commonly have altered protein expression. Also, transfection of a wild-type copy of the mutated gene in patient cells (for example, in EBV-B or HSV-T transformed cells) restoring the protein

function can confirm a possible loss-of-function mutation (Martínez-Barricarte et al., 2016). Furthermore, new techniques such as CRISPR/Cas9 open the possibility of reversing the mutation in patient cells or mutating control to confirm that the phenotype that is observed in the patient is due to the mutation.

Diagnostic algorithm for IL-12/IFN- γ circuit defects

Set up and performance of specific functional techniques for MSMD diagnosis is not trivial. Besides of the technical limitations, interpretation of the results can also be challenging. Especially in low-income countries, the needed infrastructures and equipment's could be also limiting, as there is a need to work in sterile conditions with high cost equipment and consumables, specifically in relation to flow cytometry or some cytokine detection techniques. MSMD diagnosis is usually only possible in specialized immunology laboratories. Currently there is a broad array of available tests for MSMD diagnosis, each one with different strengths and limitations (Esteve-Solé et al., 2018).

Considering price, working hours and complexity in the interpretation of results, reviewed by Esteve-Solé et al. (Esteve-Solé et al., 2018), we propose a step-by-step algorithm (Fig. 2) for MSMD diagnosis in the routine practice after clinical suspicion: (1) discard other more frequent intramacrophagic-susceptibility-conferring PIDs by performing T cell phenotyping, proliferation assessment and oxidative burst evaluation, (2) performance of cytometric determination of the presence of IL-12R β 1, IFN- γ R1, IFN- γ R2 and, when possible, of STAT1 phosphorylation in response to IFN- γ and IFN- α , (3) genetic evaluation, whether by targeted Sanger sequencing when functional evaluation suggests a clear candidate gene or by NGS if no causative gene is identified, and (4) functional confirmation of the genetic result, which normally needs to be performed in the context of a research laboratory. Nevertheless, only genetics with a functional confirmation of the identified variant will lead to a definitive diagnosis. WES or WGS is recommended for cases with no molecular identification of the defect.

Concluding remarks

Like in other IEL, MSMD is an increasing group of disorders with clinical and immunological heterogeneity. Since the first description of *IFNGR1* deficiency in 1996 (Jouanguy et al., 1996) years, the number of genetic defects included in MSMD has increased to the current 18 genes. Nevertheless, almost 50% of patients with suspected MSMD do not have a confirmed genetic diagnosis up to date. Functional testing of the IL-12/IFN- γ circuit may help confirm a functional impairment explaining the increased susceptibility to mycobacterial disease when genetics is not concluding. Besides, functional testing is necessary after the identification of new unreported mutations. Functional testing of the IL-12/IFN- γ circuit is challenging, it has its particular tips, which we have tried to summarize in the document. Some of these techniques are limited by the timing and the requirement of qualified staff, making the full diagnosis of MSMD suited for specialized immunology laboratories. Genetic approaches are gaining ground and could overcome these limitations. Nevertheless, genetic results usually need a functional confirmation of the identified mutation.

MSMD should be considered in patients with significant infection (severe, disseminated, or recurrent) after BCG vaccination and infection by mycobacteria, particularly EM, especially in combination with Salmonella, Candida or virus. Besides, the knowledge of other conditions that can lead to susceptibility to mycobacterial diseases is relevant and must be considered in the differential diagnosis. These include: acquired causes of immunodeficiency (anti-TNF- α biological treatment, jak-inhibitors, hematological disorders, and neutralizing anti-IFN- γ antibodies), and other IEL: T cell defects, GATA-2 deficiency and chronic granulomatous disease first need to be ruled out. Once these entities are ruled-out, MSMD-specific evaluation should be started. Tests performed and their order may depend on laboratory facilities, technical staff, and clinical orientation.

Genetic and/or functional confirmation of MSMD is of utmost importance since specific therapeutic measures can be applied to improve infection resolution rate and patient's prognosis and quality of life. This is exemplified by complete deficiency of IFN- γ R where the only curative treatment attempted is HSCT; on the other hand, most other forms of MSMD will benefit from prolonged anti-tuberculous treatment to which exogenous hrIFN- γ therapy can be added—even partial defects of IFN- γ receptors respond to exogenous hrIFN- γ therapy (Bustamante et al., 2014; Dorman et al., 2004; Holland, 2000). When a member of a family is diagnosed with MSMD, BCG vaccination in family members should be avoided until a genetic defect has been ruled out. It is also important to consider that some MSMD etiologies have incomplete penetrance, meaning that not all the individuals presenting the mutation will present the clinical phenotype and genetic counseling in these patients is challenging.

Nomenclature

AGS	Aicardi-Goutières syndrome
AIDS	Acquired immunodeficiency syndrome
AVA	Antiviral assay
BCG	Bacillus Calmette-Guérin
CANDLE	Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature
CSF	Cerebrospinal fluid
CPE	Cytopathic effect
CFP 10	Culture filtrate protein 10
DsRNA	Double-stranded ribonucleic acid
ESAT 6	Early secretory antigenic target 6
ELISA	Enzyme-linked immunosorbent assay
ELISPOT	Enzyme-linked immunospot assay
EMCV	Encephalomyocarditis virus
GFP	Green fluorescent protein
IFN	Interferon
ISG	Interferon-stimulated genes
IL-1	Interleukin 1
JAK	Janus kinase
PBMC	Peripheral blood mononuclear cells
PKR	Protein kinase R
PPD	Purified protein derivatives
qPCR	Quantitative polymerase chain reaction
MHC	Major histocompatibility complex
NOMID	Neonatal onset multisystem inflammatory disease
NTM	Non-tuberculosis mycobacteria
RD 1	Region of difference 1

RA	Rheumatoid arthritis
RGA	Reporter gene assay
SAVI	STING-associated vasculopathy with onset in infancy
SFV	Semliki forest virus
SiMoA	Single molecule array
SS	Sjögren's syndrome
STAT	Signal transducer and activator of transcription
SLE	Systemic lupus erythematosus
SLEDAI	Systemic lupus erythematosus disease activity index
TST	Tuberculin skin test
TYK2	Tyrosine kinase 2
UCTD	Undifferentiated connective tissue disease
VSV	Vesicular stomatitis virus

Introduction

Interferons (IFNs) are a group of cytokines with potent antiviral properties that are released by nearly all cells of vertebrate organisms following a viral infection. There are three types of interferons, namely type I, type II and type III interferons. This classification is strictly based on the receptor type the interferons bind to upon their release (Rius-Rocabert et al., 2019). Type I interferons are the largest and the most studied type of interferons and comprise of 13 distinct IFN- α subtypes and an IFN- β subunit. Thus, 13 distinct IFN- α genes are encoded within the human genome whereas a single gene encodes for IFN- β (Rentsch and Zimmer, 2011). Cells are able to sense viral infection via their pattern recognition receptors such as the retinoic acid inducible gene I (RIG-I) which causes the IFN-dependent genes to be transcriptionally activated. Secreted interferon- α and interferon- β produce similar effects by binding to a common, widely distributed IFN- α/β receptor that cause the activation of the JAK/STAT signal transduction pathway and an upregulation in the transcription of "IFN-stimulated genes" (Der et al., 1998; Rentsch and Zimmer, 2011).

IFN- γ is used to represent the type II interferons and IFN- λ is used to designate type III IFNs. Both cytokines possess antiviral activity by binding to different and distinct receptors. Type I and Type III IFNs produce similar activated antiviral genes via transcription. The site of action of Type III interferons is primarily in epithelial cells (Sommerey et al., 2008). The innate immune system protects epithelial tissues from viral infection through the action of Type III IFNs (Pott et al., 2011).

In the event of a viral attack on a human host, interferons are inducible cytokines that mediate the immune antiviral and anti-proliferative response against the virus (Burdick et al., 2009). Type I interferons act in an autocrine manner to terminate the replication of virus in infected cells. Type I interferons also act in a paracrine manner to block viral replication within the host by inducing an antiviral state in healthy uninfected cells. Type I interferons exhibit some effect on cell proliferation and differentiation, promotion of programmed cell death, modulation of the immune system and inhibition of angiogenesis as reported by Maher et al. (2007).

Type I IFNs express various immunomodulatory effects, which range from modulation of T cell response, expression of class I major histocompatibility complex (MHC) and an upregulation of the differentiation of dendritic cells (Rönblom and Alm, 2003). Type I interferons are inducible forms of cytokines that are principally involved in the immune protection against invading viruses and intracellular bacteria (Lamot et al., 2019).

Overstimulation or defective regulation of the expression of type I IFNs can lead to sustained type I interferon activity which has profound deleterious effects on the body (Gresser et al., 1980; Hunt et al., 2014). Aicardi-Goutières syndrome (AGS), a genetic auto-inflammatory condition, had the first hallmark feature of sustained type I IFN activity. It affects the central nervous system in a way that mimics neurological manifestations of congenital viral infection. Persistent activity of IFN I in AGS led to the discovery of a novel group of monogenic auto-inflammatory diseases collectively referred to as type I interferonopathies (Crow, 2011, 2015; Crow and Manel, 2015; Volpi et al., 2016).

Subsequently, dysfunctional activation of type I IFNs has been closely linked to the etiology of many systemic complex auto-inflammatory conditions including systemic lupus erythematosus (SLE), Sjögren's syndrome (SS) and rheumatoid arthritis (RE) among others (Batterham et al., 2003; Muskardin and Niewold, 2018; Lamot et al., 2019).

Recent evidence supports the assertion that type I IFNs are implicated in both the disease initiation and progression of systemic lupus erythematosus. This consensus was arrived at because numerous studies showed a positive association between elevated levels of IFNs and SLE disease severity (Von Wussow et al., 1988; Yee et al., 1990). A prior study reported a significant correlation between raised IFNs levels and SLE disease activity as 71% of participants with active disease had marked serum IFNs levels compared with 21% of participants with inactive disease showing raised serum IFNs levels (Hooks et al., 1979). Subsequent studies corroborated the link between raised serum IFNs levels and SLE disease activity (Friedman et al., 1982; Kim et al., 1987). A clinical observation of SLE patients by Bengtsson and his team provides evidence of a positive correlation between the serum IFN- α levels and Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) scores which further suggests the intricate role of the type I IFNs in the pathogenesis of SLE (Bengtsson et al., 2000).

Data obtained from genetic studies show a clear polymorphism in SLE-linked kinase cascade signaling genes for type I IFNs and in IFN-regulated genes (IRGs) (Baechler et al., 2003; Bronson et al., 2012). Gene expression profiling studies have revealed an IFN signature, or a substantial upregulation of mRNA transcripts encoded by IRGs, in some SLE, RA and other auto-inflammatory disease patients (Baechler et al., 2003; Higgs et al., 2011).

Rönnblom and his team hypothesized that, dysregulation in the signaling mechanism of type I interferons may override the immune tolerance mechanism leading to a progressive production of autoantibodies (Bengtsson et al., 2000; Rönnblom and Alm, 2003).

In many autoimmune diseases which involve the production of autoantibodies, a significant proportion of patients show an elevated dominant type I interferon signature when analysis of their peripheral blood mononuclear cells (PBMCs) or serum is carried out. Such diseases include systemic lupus erythematosus (SLE), dermatomyositis, rheumatoid arthritis and multiple sclerosis (Crow, 2007; van der Pouw Kraan et al., 2007).

In many autoimmune diseases like systemic lupus erythematosus, patients with active disease show an over-expression of type I IFN inducible transcripts and increased levels of type I interferons. Analysis of whole blood samples or PBMC of such patients showed a dysregulated expression of inducible type I interferons (IFN) known as the Interferon (IFN) signature (Becker et al., 2013). An IFN signature has been implicated as a marker for SLE as IFN levels were increased in serum samples obtained from SLE patients, which showed a positive correlation with SLEDAI scores and clinical disease manifestations (Becker et al., 2013).

Before the advent of direct measurement of type I IFN- α in physiological samples, the relationship between increased type I IFN activity and various diseases was ascertained based on *in vitro* analysis, which measures the downstream effect of type I IFN activation. This involves analyses of antiviral and/or transcriptional activity caused by type I IFN activation. Concurrent use of these functional assays together with emerging assays that directly quantify type I IFNs in biological samples will revolutionize our approach towards understanding the vital role of type I IFNs in type I IFN-mediated diseases and their management (Rodero and Crow, 2016; Picard and Belot, 2017).

With this background, we reviewed the various laboratory assay procedures used to identify interferon signatures, which will aid in the study and diagnosis of these Type I interferonopathies like SLE and RA. In addition, we assessed the advantages and limitations of the various identification and quantification assays for interferons (IFNs).

Immunoassay of interferons – Direct assay

Enzyme expression assay

Immunobioassay can be used to quantify the amount of IFNs by detecting the expression of IFN-inducible proteins. Another method to quantify the amount of IFNs is by measuring directly the level of IFN-inducible proteins that possess inherent enzymatic activity. A wide range of these enzymes, which includes 2'-5'-oligoadenylate synthetase (2-5A synthetase), Protein kinase R, MxA GTPase among others, may form the basis of this bioassay (Meager, 2002). Uno and his team developed an assay for IFN- α by inducing and measuring the levels of 2-5A synthetase. This bioassay however showed weak sensitivity to IFN- β and IFN- γ (Uno et al., 1998).

Nonetheless, a specific bioassay exists for type II IFN that quantifies the levels of kynurenine to assess the amount of type II IFN present in a sample. Type II IFN specifically induces an enzyme, indoleamine 2, 3-dioxygenase (IDO). This enzyme is solely responsible for the conversion of L-tryptophan to N-formyl kynurenine (NFK). Hence, a specific biological assay was designed to quantify kynurenine, the product of NFK hydrolyzation, in an IFN- γ -induced human glioblastoma cell line, 2D9 (Däubener et al., 1994).

A limitation of the enzyme expression assay is that, it requires several manipulations in order for accurate quantification of the enzyme product (Meager, 2002).

Enzyme-linked immunosorbent assay (ELISA)

In the qualitative and quantitative analysis of soluble proteins such as interferons, Enzyme-Linked Immunosorbent Assay (ELISA) is the most widely employed method for the detection and quantification of such cytokines. Interferons are cytokines that have low concentration in biological samples and hence requires ELISA tests that are able to detect cytokines up to picomolar concentration levels. This immunoassay detects interferon levels in response to specific antigens in whole blood culture system. Sandwich enzyme immunoassay (EIA) utilizes two monoclonal antibodies to detect levels of IFNs in biological samples (Rothel et al., 1990).

Advantages of enzyme-linked immunosorbent assay

This approach of soluble protein assay is rapid and can be carried out within approximately 4 h. It comes in a ready-to-use kit and has a high throughput and hence many samples can be analyzed within the shortest possible time which makes it ideal for clinical detection and quantification of IFNs (Lamot et al., 2019).

Demerits of enzyme-linked immunosorbent assay

It has limited sensitivity and can only measure type I interferons to the picomolar-concentration, which is greater than the concentration of IFNs in physiological samples. It also has low specificity and hence a separate assay is needed to evaluate the concentration of each subtype of type I interferons due to the limited sensitivity in detecting individual type I IFNs (Dolen and Mathur, 1995; Jabs et al., 1999).

Immunoassays such as ELISA are mostly accurate and precise when used to measure IFN levels *in vitro* but lose such sensitivity when used to measure IFN levels in patient samples. This can be attributed to the presence of inhibitors such as heterophile antibodies, or soluble moieties of IFN- α/β interfering with sensitivity. The absolute amount of type I IFN determined using immunoassays like ELISA does not necessarily reflect the proportion of biologically active type I IFN in the sample (Vrolijk, 2005).

Single molecule array (SiMoA) digital ELISA

The SiMoA digital ELISA is a new technology that facilitates the detection and quantification of biological concentration of IFN- α at the attomolar level. This technology also allows for the identification and quantification of all 13 IFN- α in one assay (Lamot et al., 2019).

In this assay, single molecules of various IFN- α are captured with enzyme-linked autoantibodies produced by the patient and linked to paramagnetic beads, which are detected, as in an ELISA, with an enzyme-generated fluorescent product. The autoantibodies are tested for cross-reactivity with other subtypes of IFNs (Rissin et al., 2010; Yeung et al., 2016).

The SiMoA has been employed successfully to measure IFN- α protein in healthy individuals without viral infection and those with viral infections. It has also been utilized to measure the levels of IFN- α in various monogenic type I interferonopathies patients that show an IFN signature (Rodero et al., 2017).

The IFN- α protein concentration is measured using the SiMoA correlated well with functional type I IFN activity as determined by a cytopathic protection assay or qPCR detection of six Interferon-Stimulated Genes. SiMoA has been used to establish an associative relationship between high circulating levels of IFN- α and increased severity of the clinical presentations of SLE patients (Rodero et al., 2017).

Advantages of the SiMoA digital assay

The SiMoA has a very high sensitivity that allows the bioanalysis of IFNs at low abundance concentrations. It has been utilized to measure interferon concentrations at the attomolar level, which is precise enough to quantify all the various subtypes of IFN α in a single assay (Rodero and Crow, 2016).

Disadvantages of the SiMoA digital assay

There is increased cost and risk associated with the adoption and implementation of this new technology in routine clinical analysis. The SiMoA is also a single source technology and this may serve as an impediment to its extensive use for type I interferon detection across various clinical and laboratory settings (Chunyk et al., 2018).

Bioassay/functional assay of interferons – Indirect assay

One of the notable biological activity induced by interferons is their antiviral activity on which they were originally defined. The biological response to IFN is initiated when IFN binds to specific cell surface receptors and causes the activation of downstream cytoplasmic signal transduction pathways. The biological response is manifested after the expression of an array of 'IFN-inducible' genes (Sen and Ransohoff, 1993; Stark et al., 1998). Antiviral effect has been identified as one of the manifestations of expression of these 'IFN-induced genes.' Other biological activity induced by IFN includes proliferation and replication of body cells, modulation of cell differentiation, regulation of immune response and other functional cellular activities (Meager, 2002).

Different IFN-induced proteins have been identified which play vital roles in suppressing viral replication and propagation. 2-5A synthetase, an IFN-induced enzyme catalyzes the formation of an oligonucleotide, ppp(A2'p)nA(2-5A). This oligonucleotide is required to activate endonuclease RNase L, which subsequently damages viral mRNAs required for the replication of some RNA viruses like the Mengo virus (Lengyel, 1982; Rice et al., 1985; Samuel, 1987; Kumar et al., 1988; Zhou et al., 1993).

Another dsRNA-dependent antiviral protein kinase, PKR, is induced by type I interferons. It causes phosphorylation and inactivation of the peptide initiation factor, eIF2, required for the translation of messenger RNAs of viruses (Lengyel, 1982; Samuel, 1987). Replication of rhadoviruses and reoviruses like vesicular stomatitis virus (VSV) are specifically inhibited by the PKR antiviral mechanism (Gupta et al., 1982; Samuel, 1987).

Antiviral assays (AVA)

Historically, antiviral bioassays were the first identified biological assays designed to ascertain the relative potency and functional activity of various IFN preparations. There exist a diverse range of cell or viral systems and assay protocols utilized to prepare an antiviral assay. Some mammalian and human cell lines are ideal for the design of antiviral assay with high sensitivity (Table 1). It is worth noting that, not every cell line is suitable for AVA because some tumor cell lines possess a defective IFN response system. The defect may be linked to the absence of some effector molecules in the IFN-mediated signal transduction pathway (Meager, 2002). The mutant adenocarcinoma cell line lacks TYK2 whereas the melanoma cell lines lack STAT1, STAT2 and p48 making both cell lines unsuitable for antiviral assay (Pellegrini et al., 1989; Wong et al., 1997).

Table 1 Suitable mammalian cell lines and cytolytic viruses used in various antiviral assay protocols.

<i>Antiviral Assays</i>		
<i>Cell line</i>	<i>Virus</i>	<i>IFN</i>
Madin–Darby bovine kidney cell line (MDBK)	Vesicular Stomatitis Virus (VSV)	Human, bovine
Human lung carcinoma cell line	(A549) VSV or Encephalomyocarditis Virus (EMCV)	Human
Human amniotic cell line (WISH)	VSV, EMCV, Semliki Forest Virus (SFV) or Sindbis virus	Human
Human cervix carcinoma cell line (HeLa)	EMCV or VSV	Human
Human larynx carcinoma cell line (Hep2)	EMCV, VSV, or Mengovirus	Human
Human foreskin diploid fibroblast cell line	VSV, EMCV, or Mengovirus	Human
Human amnion-derived cell line (FL)	VSV, EMCV, Mengovirus, or Sindbis virus	Human
Human glioblastoma cell line (2D9)	EMCV	Human
Murine fibroblastic cell line (L929)	VSV or EMCV	Murine

VSV: Vesicular stomatitis virus; EMCV: Encephalomyocarditis virus; SFV: Semliki forest virus.

Adapted from Meager A (2002) Biological assays for interferons. *Journal of Immunological Methods* 261(1–2): 21–36.

In every antiviral assay, it is essential to measure the level of inhibitory effect of IFN on viral replication. The parameters to look out for include reduction of viral yield, reduction of viral cytopathic effect (CPE), a decrease in viral plaque formation and viral RNA synthesis as well as a decrease in the production of viral proteins (Meager, 2002).

Anthony Meager described two methods widely used in the quantification of IFN bioactivity. The first method involves measuring the inhibition of the cytolytic effect of the virus whereas the second method depends on the quantification of viral reporter proteins (Meager, 2002).

Cytopathic protection assay

This antiviral assay indirectly quantifies type I IFN concentration by measuring the reduced cytopathic effect or diminished viral growths in cell lines transfected with cytolytic viruses. For example, the concentration of patients' cerebrospinal fluid (CSF) or serum that offers 50% protection of Maldin-Darby bovine kidney cells transfected with vesicular stomatitis virus (VSV) can be utilized to quantify the amount of type I IFNs (Gresser et al., 1974; Lebon et al., 1988). It relies on the antiviral properties of type I IFNs to estimate the amount of IFNs in a solution by its ability to inhibit viral replication in a cell culture. A basic definition for 1 IFN unit is the quantity of cytokines needed to prevent a viral-induced cytopathic effect in 50% of cells in culture (Familletti et al., 1981; Rubinstein et al., 1981). The cytopathic protection assay was the first assay method used to characterize AGS, the first identified monogenic type I interferonopathy (Goutières et al., 1998).

A limitation of the cytopathic protection assay is its reliance on live viruses, which cause biohazard safety concerns due to risk of accidental infection. Also, it is time-consuming and takes a duration of more than 24 h to complete a single assay (Lamot et al., 2019).

Recombinant replicon assay

This novel type I IFN bioassay serves as a useful alternative to the cytopathic protection assay, which uses live viruses for the bioassay. It relies on a viral replicon- based bioassay that has the advantage of using disabled or inactivated propagation-incompetent virus like VSV replicon linked with two reporter proteins for the bioassay (Rentsch and Zimmer, 2011). Recombinant replicon assay is biosafe because unlike conventional antiviral assays, there is no need to institute appropriate biosafety hazard measures since the replicon virus employed is inactivated and non-infectious. RNA replicons replicate solely within the cytosol and produce no complementary DNA intermediates. As such, in instances of accidental infection, the risk of integration into the host chromosomal DNA is avoided as the replicon particles cannot produce infectious progeny (Rentsch and Zimmer, 2011).

Transcription-stimulating activity

Reporter gene assay

In contrast to conventional antiviral activity assays which rely on the functional cytoprotective effect of IFNs against cytolytic viruses, reported gene assay (RGA) quantifies type I IFNs based on their ability to upregulate several downstream effector genes called interferon-stimulated genes (Der et al., 1998). The IFN-responsive promoter of Mx gene is mostly utilized due to its sensitivity and its ability to express low background of various interferon stimulated genes (ISGs) (Holzinger et al., 2007). Proteins encoded by ISGs such as dsRNA-activated protein kinase mostly mediate the action of IFNs.

In the reporter gene assay, there is a measurement of the fluorescence intensity produced by viral-encoded reporter proteins such as the green fluorescent protein (GFP) during viral replication in a suitable cell culture medium (Grover et al., 2003; Voigt et al., 2013). In this modified bioassay, it is prudent to use viruses with slow lytic effects to provide adequate time to measure the fluorescent protein production without interfering with the viability of the cell line. In using this method, it is not a necessity to fix cells and multiple time points can be analyzed for individual bioassays. The indirect quantification of IFN-induced protection against the lytic virus is measured by the fluorescent intensity. This is obtained by calculating the ED₅₀, which is the amount of IFN that is able to cause a 50% reduction in fluorescence (Rius-Rocabert et al., 2019). This method may utilize green fluorescent protein (GFP)-producing viruses that allows the quantification of reduction in viral titers by counting GFP-positive cells, either manually or by the use of a flow cytometer (Kuri et al., 2010).

VSV*ΔG (Luc), a VSV recombinant replicon encoding the reporter protein firefly luciferase, allows the quantification of type I IFNs in a relatively shorter period of time (5 h) compared to conventional type I IFN assays assuming the suitable cell line is selected for the assay. Conventional antiviral assays like the CPE often take over 24 h to carry out a single assay as it relies on the inhibition of cytopathic effects. However, in bioassays utilizing the firefly luciferase reporter, the firefly reporter expression has high sensitivity and it can be easily detected long before any cytopathic effect becomes visible (Rentsch and Zimmer, 2011).

Other common forms of reporter Gene assay employs HeLa or Vero cells lines transfected with a luciferase gene and under the control of a type I IFN inducible promoter (Canosi et al., 1996; Seo et al., 2009). The luciferase reporter activity in transfected cell lines is influenced by the extent to which replication or transcription of the RNA replicon is inhibited. Therefore, lower luciferase levels should directly correspond to the higher degree of reduction in viral RNA replication by the type I interferon (Rentsch and Zimmer, 2011).

Recently developed cell lines like RAW-Blue ISG and B 16-Blue IFN α/β are designed to produce a soluble gene like embryonic alkaline phosphatase upon induction by type I IFN which can then be quantified by using multi-well plate spectrophotometers or luminometers. It is a useful alternative method but its use in clinical setting is limited due to lack of standardization and complexity (Rees and Lowy, 2018).

A major shared limitation of both the reporter gene assay and commercially available ELISA tests is their restriction to a specific host. This is evident because interferons bind to their receptors in a species-specific manner (Kuri et al., 2010). One other limitation of the RGA is that, it considers a unit of IFN as the amount of interferon which is able to protect 50% of a cell culture from the virus without any regards to the percentage of the cells that have not been infected or have been infected in its early stages by the virus and hence are producing very low viral reporter proteins compared to the ones infected by the virus in its later stages (Stark et al., 1998).

Protocol 1 – The Hil3 reporter assay

This protocol was adopted from an investigation by Dall'Era and her team, who investigated the correlation between type I interferons and the clinical signs and symptoms of SLE patients (Dall'Era et al., 2005).

In this reporter assay, a plasmid encoded with an IFN stimulated response element – luciferase (ISRE-Luc) and a neomycin resistance gene were transfected into a human cell line Hil3. The Hil3 were cultured in a 96 well plate and incubated overnight in Dulbecco's modified Eagle's medium. The growth media and blood samples from either normal or SLE patients were mixed and cultured for 18 h. A three-step serial dilution of IFN in triplicate at specified concentration was included on each plate. Addition of a lysis buffer to the luciferase substrate halted the reaction. The substrate solution was added to each well and read on Top Count for 10 min. The count per second (cps) at each interferon concentration were recorded and the interferon concentration (or cps) in each sample was estimated from the IFN titration curve using appropriate software with linear regression parameters (Dall'Era et al., 2005).

An advantage of the Hil3 reporter assay is that, it is able to identify and quantify multiple sub-types of type I interferons such as natural leucocyte IFN that contains multiple IFN- α subtypes and IFN- β . It has been established by Dall'Era and her team that various type I IFN moieties have the propensity to provoke a luciferase response (Dall'Era et al., 2005). A limitation of the Hil3 reporter assay is that it shows minimal luciferase response to IFN- γ with a faint traceable signal at even the highest concentration of IFN- γ utilized for test (Dall'Era et al., 2005).

Interferon stimulated genes (ISG) expression assay

The qPCR biomarker assay is a form of quantitative reverse transcription PCR employed to measure the IFN signature in patients with interferonopathies such as SLE (Morimoto et al., 2011). qPCR and the newly engineered NanoString technology have been widely employed to analyze differential expressions of subtypes of ISGs in whole blood and to a lesser degree in disease-related tissues (Rice et al., 2013, 2017; Kim et al., 2018).

Oligonucleotide array was first used to identify an 'IFN signature,' a set of inducible genes in SLE patients (Baechler et al., 2003; Bennett et al., 2003). The IFN signature has then been validated in other studies of SLE patients and in other autoimmune inflammatory diseases such as Rheumatoid arthritis (RA), dermatomyositis (DM) and Sjögren's syndrome (SS) (Higgs et al., 2011; Lübbbers et al., 2013; Bodewes et al., 2018). It was unsurprising that an IFN signature was identified in patients with AGS, the first identified type I interferonopathy (Rice et al., 2012). A type I 'Interferon score (IS)' was created from six IFN-stimulated genes, ISGs – (IFI27, IFI44L, IFT1, ISIG15, RSAD2 and SIGLEC1), that showed the highest differential expression in AGS patients

compared with healthy control subjects. The interferon score was calculated based on the relative intensity of expression of these ISGs. The IFN score can be used as single diagnostic or prognostic value for various IFN-induced interferonopathies (Rice et al., 2012, 2013).

This six-gene assay was subsequently utilized in a prospective case-control study to quantify type I interferon activity in 82 patients with mutations in a single gene with established association to AGS - (RNASEH2B, RNASEH2C, SAMHD1, ADAR and TREX1, RNASEH2A). The expression of six IFN-stimulated genes was quantified using qPCR, and the median fold change relative to the median of healthy patients was utilized to develop an interferon score for every individual patient (Rice et al., 2013). The interferon score was positive in 90% of the AGS patients. Positive or negative IFN score showed good correlation with patient's serum IFN activity measured using a viral cytopathic assay in 12 of the 14-paired samples. Neutralization assays carried out with anti-IFN- α and anti-IFN- β antibodies depicted that detectable anti-viral activity was primarily due to the action of IFN- α (Rice et al., 2013).

NanoString Technology allows for the quantification of larger subsets of ISGs, which are typically 28 genes. It does this at a faster pace with easily reproducible results. The principle behind this assay is that, it uses molecular 'barcodes' to identify and simultaneously count up to several hundred unique target gene sequences or mRNA transcripts in a single hybridization reaction. It utilizes complementary DNA synthetic oligos to directly bind, capture and tag mRNA for counting without the need for reverse transcription or amplification (Geiss et al., 2008; Kim et al., 2018). The 28 target genes were chosen from whole blood microarray expression profiles of two patients, one with CANDLE and the other with chronic hepatitis C following IFN-2 α therapy. This panel has then been validated in treatment-naïve patients with genetic predisposition to diseases mediated by type I IFN (CANDLE, $n = 11$; SAVI, $n = 7$) or IL-1 (Neonatal onset multisystem inflammatory disease, NOMID, $n = 16$) and healthy individuals ($n = 26$). Interferon scores calculated from the 28 target genes suggested a significant difference between CANDLE and SAVI compared with NOMID and healthy individuals. In the samples tested, a high correlation was observed between repeated measures with no variation in gender or age or diurnal variation (Kim et al., 2018; Lamot et al., 2019).

The NanoString nCounter gene expression system has some advantages over conventional qPCR. It is quicker, and has a higher throughput, which makes it an ideal assay for daily clinical assessment and quantification of IFN-induced gene expression in patients, especially those with defined interferonopathies (Kim et al., 2018). However, the ability of NanoString and qPCR to measure 6 ISGs offer similar results or outcomes in terms of analytical performance (Pescarmona et al., 2019).

Laurent and his team developed a two-score system, which considered the expression of two distinct sets of genes instead of the conventional single set of genes to calculate the interferon score. The IFN scores, designated as IFN-score-A and -B, with some genes overlapping were selected from 31 ISGs associated with SLE. The scores have been validated in a cohort of 279 patients with SLE, UCTD, RA and in 49 healthy controls. IFN-A score distinguished SLE patients from both RA and healthy individuals, whereas IFN-B score differentiated both SLE and RA from healthy individuals. This shows that, calculation of interferon scores based on two or more sets of genes showed higher disease specificity compared with interferon scores calculated based on a single assay (Chiche et al., 2014; Lamot et al., 2019).

One major limitation of the ISGs expression assay is that there is no consensus or standard ISGs subset for the calculation of interferon score (Lamot et al., 2019).

Interferon- γ assay for tuberculosis

One major hindrance to the management of tuberculosis worldwide is the diagnosis and treatment of latent tuberculosis. *Mycobacterium tuberculosis* bacilli infection produces no symptoms in individuals with latent tuberculosis. It is estimated that roughly one-third of the world's population is latently infected with tuberculosis and about 10% will get active disease over their lifetime. Individuals with latent tuberculosis serve as a source from which new active cases can arise from (Styblo, 1980; Jasmer et al., 2002; Tufariello et al., 2003).

Prior to the advent of newer diagnostic methods for detecting latent tuberculosis infection, the tuberculin skin test (TST) was routinely used to diagnosis symptom-free TB infection (Huebner and Schein, 1993; Goldstein et al., 2002). The principle behind the TST is to measure the level of cell-mediated immune response via the intensity of a delayed-type hypersensitivity response to purified protein derivatives (PPD). PPD is a pool of antigens from *M. tuberculosis*, *M. bovis*, Bacillus Calmette-Guérin (BCG) and several other non-tuberculosis mycobacteria (NTM) (Huebner and Schein, 1993; Andersen et al., 2000; Goldstein et al., 2002). TST therefore showed low specificity in NTM endemic populations and low sensitivity in immunocompromised patients (AIDS, malnutrition and advanced tuberculosis) (Huebner and Schein, 1993; Andersen et al., 2000; Winer et al., 2009).

Interferon- γ assay is a new *in vitro* T-cell- based assay that serves as the first alternative option to TST in diagnosing latent tuberculosis infection (Dockrell and Weir, 1998; Andersen et al., 2000; Lalvani, 2003). The principle behind the interferon- γ assay is that, the T cells of tuberculosis antigen sensitized-individuals produce interferon- γ when they become re-exposed to the mycobacteria antigen (Andersen et al., 2000). Marked elevation of interferon- γ levels upon re-exposure signifies the presence of tuberculosis infection. The initial research relied on PPD as the stimulating antigen, but current assay methods focus on *M. tuberculosis* specific antigens like the early secretory antigenic target 6 (ESAT 6) and culture filtrate protein 10 (CFP10) (Andersen et al., 2000; Mawa et al., 2004). The region of difference 1 (RD-1) of the *Mycobacterium tuberculosis* genome encodes for the production of these stimulating proteins which makes them more specific to *Mycobacterium tuberculosis* compared to PPD, as they are not found in any BCG strain or NTM species (Sørensen et al., 1995; Andersen et al., 2000).

The two most widely used commercial interferon- γ assays are the QuantiFERON-TB assay and the T SPOT-TB assay. Both tests indirectly measure cell-mediated immunity by measuring the amount of interferon- γ produced from T cells upon exposure to a tuberculin antigen using methods such as ELISA and enzyme-linked immunospot (ELISPOT) assay (Mazurek and Villarino, 2003).

Earlier versions of the QuantiFERON-TB assay utilized whole-blood assay that measured interferon- γ response upon stimulation with PPD using ELISA. The enhanced QuantiFERON-TB Gold assay utilizes ESAT 6 and CFP 10 as the stimulating antigens (Mazurek and Villarino, 2003). The T SPOT-TB assay uses peripheral blood mononuclear cells (PBMCs), ESAT 6 and CFP 10 as stimulating proteins, and ELISPOT to detect the number of T cells producing interferon- γ (Lalvani, 2003). Both assay methods use cellular immune-based tests to measure interferon- γ response with shorter incubation periods of within 24–48 h compared to 5–6 days in most non-commercial in-house assays (Lalvani, 2003).

Advantages of interferon γ assay

Interferon- γ assay has several advantages compared to the conventional tuberculin skin test (TST). Interferon- γ assay is an *in vitro* test, which makes it more objective because it does not require the measurement of skin induration, which gives rise to reader bias and error. The patient also requires just a single visit, as there is no follow-up visit like the tuberculin skin test. RD1-based interferon- γ assay method is more specific than TST which uses PPD as a stimulating antigen (Andersen et al., 2000; Lalvani, 2003). RD1-based interferon- γ assays has better correlation with exposure to *M. tuberculosis* and relatively minimal cross-reactivity to previous BCG vaccination and NTM infection (Pai et al., 2004). The use of a mixture of antigens for the interferon- γ assay enhances both the sensitivity and specificity of the assay. This is clinically relevant because sensitive assays for tuberculosis infection are favorable for immunocompromised patients who have a higher chance of getting a false-negative TST test and are at a greater risk of progression to active tuberculosis infection (Ravn et al., 2004; Richeldi et al., 2004). Some evidence suggest that interferon- γ assay can be used to potentially identify latent tuberculosis patients who have a greater susceptibility of developing active tuberculosis infections (Pai et al., 2004).

Disadvantages of interferon- γ assay

The impact of interferon- γ assay in monitoring treatment remains unclear, as current evidences show inconsistencies. This has partly been attributed to the variability in interferon- γ methods used. Interferon- γ assays are more expensive than the TST and hence, financial burden will be a crucial limitation in determining the global utilization of this newer and more efficient assay (Pai et al., 2004).

Recent developments and future perspectives

Concerning the use of interferon- γ assay for the diagnoses of tuberculosis, future research must focus on improving the sensitivity of RD1-based interferon- γ assays, without compromising its high specificity. Subsequent research must seek to find antigens that are more specific and/or a cocktail of antigens for the interferon- γ assay.

Again, a comparative study should be carried out to assess the sensitivity and accuracy of both the ELISPOT and ELISA formats. Research should be carried out to compare both sensitivity and specificity of the short (24–48 h) incubation assay and the long (5–6 days) incubation assay.

The application of the SiMoA technology in diagnosing and monitoring of interferon levels in patients with various interferonopathies and other diseases requires further clinical evaluation and validation in additional patient cohorts.

Conclusion

An Interferon signature, described as an increased expression of interferon-stimulated genes (ISGs), is peculiar characteristic of a group of autoimmune inflammatory conditions called Type I interferonopathies, which includes RA, SS and SLE among others. The assays for the detection of an interferon signature have undergone modification throughout the years in an attempt to produce highly sensitive and specific assays. Methods that are used to identify activated type I interferons can be grouped into direct measurement of type I IFN concentration through immunoassays such as ELISA and indirect measurement of IFN via its functional antiviral activity or induced gene expression. Interferon signature analysis can be used clinically via the determination of IFN score to diagnose or predict the disease prognosis of patients with various type I interferonopathies. There is a direct correlation between the Levels of type I IFN and disease severity. There is a need for further research to identify newer and more robust assay methods for detection and quantification of IFNs that can be employed in the clinical setting.

Introduction

The human leukocyte antigen (HLA) system is a highly polymorphic gene complex critical in regulation of the immune system. These genes encode the human version of the major histocompatibility complex (MHC) and produce the HLA antigens found on the surface of all leukocyte cell membranes in humans. These antigens serve as recognition molecules to distinguish between self and non-self-proteins and aid in presenting the foreign antigenic proteins to the effector cells of the immune system (the T-cell lymphocytes or T-cells), all in the initiation of the immune response.

The HLA family of genes comprise about over 3.6 million bases of DNA located on the short arm of chromosome (6p21.3) and is approximately 0.13% of the human genome, containing over 200 hundred identified gene loci (Hosomichi et al., 2015; Robinson et al., 2015). The HLA genes are inherited as one complete allele from each parent (the maternal and paternal haplotypes) to form the diploid HLA genotype, specific to that individual. This specificity is also due to the polymorphic nature of the HLA genes in which the variations or polymorphisms found in the genetic sequences encoding the regions of interaction or binding between the T-cells and the HLA molecules are important for recognition of non-self-proteins and their subsequent elimination (Mayor et al., 2015). It is thought that this heterozygous nature provides an evolutionary advantage by increasing the number of potential non-self-recognition molecules and increasing the likelihood for survival of the individual.

This essential role in regulating the immune response makes the HLA genes a primary factor in transplant outcomes. These molecules are, in large part, responsible for the success or failure/rejection of organ and tissue transplants between individuals. The closer a genetic match between donor and recipient, the greater the chance for a successful transplant outcome. In addition, HLA polymorphisms are known to be associated with specific disease states or an increased risk of pharmaceutical adverse effect (Male, 2001). As a result, accurate and detailed HLA typing is critical in achieving positive outcomes.

Classification

The HLA gene family is divided into three MHC groups known as Class I, Class II and Class III molecules based on the structure and function of their gene products. Class I and II contain the HLA genes whose products include the antigen-presenting molecules while Class III contains a number of other immune system molecules such as complement components, heat shock proteins and some cytokines (Male, 2001).

MHC class I

MHC Class I proteins are transmembrane proteins located on the surface of all nucleated cells and are formed by a glycosylated alpha (α) heavy chain bound to a beta-2 (β_2) microglobulin molecule (Male, 2001). The β_2 -microglobulin molecule is a heterodimer composed of major and minor gene subunits. The degree of glycosylation and the amino acid sequences of the polymorphic heavy chain varies with haplotype, creating the variations that generate numerous sequences to form the various alleles within each HLA family. The β_2 -microglobulin portion, in contrast, is not polymorphic but is required for proper expression of the Class I HLA molecules (Male, 2001).

Since every nucleated cell expresses the MHC Class I antigens, every cell has an antigen-presenting function. Besides interacting at the heavy chain peptide binding region with generalized T-cells, previous studies have shown that a certain class of antigen-presenting T-cells, the CD8-positive cytotoxic T-cells, react with and bind to the non-polymorphic part of the MHC Class I heavy chain (Robinson et al., 2015). Some additional MHC Class I genes such as HLA-G and HLA-E encode non-classical MHC molecules which have specialized functions such protecting the fetus from the maternal immune response during gestation and antigen-presentation to other immune system cells such as natural killer (NK) cells.

The MHC Class I proteins are divided into three major and three minor subclasses shown below:

- Major subclass: HLA-A; HLA-B; HLA-C.
- Minor subclass: HLA-E; HLA-F; HLA-G; HLA-H.

MHC class II

MHC Class II proteins are usually found only on the surface membranes of antigen presenting cells such as B-cells, macrophages, dendritic cells and Langerhans cells as well as T-cells (Madden and Chabot-Richards, 2019). These molecules are composed of two glycoprotein (heavy alpha (α) and light beta (β)) chains, forming heterodimeric ($\alpha\beta$) protein receptors on the surface membranes of the cells (Male, 2001). Similar to the Class I molecules, the alpha heavy chains are polymorphic and vary in degree of glycosylation and amino acid content while the beta light chains are not polymorphic (Male, 2001). Unlike the Class I molecules, Class II molecules do not initialize antigen presentation but bind to proteins that have already been processed.

MHC Class II proteins are divided into three major and two minor subclasses shown below:

- Major subclass:
 - HLA-DP (α -chain encoded by HLA-DPA1 locus and β -chain encoded by HLA-DPB1 locus).
 - HLA-DQ (α -chain encoded by HLA-DQA1 locus and β -chain encoded by HLA-DQB1 locus).
 - HLA-DR (α -chain encoded by HLA-DRA locus and 4 β -chains) (only 3 possible per individual) encoded by HLA-DRB1, DRB3, DRB4, DRB5 loci.
- Minor subclass: DM; DO.

MHC class III

The MHC class III molecules include complement components, tumor necrosis factor-alpha (TNF- α), lymphotoxin and some heat shock proteins that are important in the inflammatory response and are used for internal antigen processing and loading of the processed antigens onto the HLA molecules of antigen-presenting cells (Male, 2001). This class is not critical in identifying HLA genotype or in its matching and is, therefore, not typically part of any HLA typing test method.

Nomenclature

Historically, HLA genotype naming was antibody-based and determined by the serological identification of HLA antigens. These antigens were assigned letters and numbers (i.e., HLA-B27) to designate the HLA gene locus name. These older techniques could not distinguish further between the alleles and the designation stopped at this level. With the advent of DNA molecular techniques, a more refined definition of HLA genes became available and a standard for nomenclature was necessary. Currently, the standard convention for HLA typing nomenclature is regulated by the WHO Nomenclature Committee for Factors of the HLA System regulations as shown in the example below (Marsh et al., 2010).

Example of nomenclature using the HLA-A*02:02:01:02 gene:

- HLA-A: The HLA prefix and HLA gene name/locus.
- *Indicates that this information is based on molecular typing results.
- 02: The allele group at the HLA locus.
- 02: The specific HLA protein.
- 01: The polymorphisms in the coding regions.
- 02: The polymorphisms in the in non-coding regions.

Letter suffixes are added to the end of the gene name, if warranted, to designate the level of protein expression. The available suffixed are shown below:

- N: a null allele with no protein expression.
- L: alleles with low protein expression.
- S: alleles that express soluble proteins.
- Q: alleles with a questionable protein expression status.

Methods

General

HLA typing was initially conducted by serological phenotypic determination. This practice has largely been replaced by either solid-phase methods such as bead assays or DNA-based molecular techniques including real-time polymerase chain reaction (PCR) and sequencing-based methods. These HLA typing methods are also used in various other applications in vaccine development, analysis of disease associations and determination of therapeutic safety and efficacy.

One concept routinely used in the description of HLA typing methods is the resolution of the results which describes the extent and details of each HLA allele. This precision is used for to choose the method of typing since different applications have different resolution requirements. For example, solid organ transplantation requires low to intermediate typing resolution where bead assays would be sufficient while bone marrow transplantation requires a high-resolution typing method such as DNA sequencing techniques (Madden and Chabot-Richards, 2019).

A low-resolution or two-digit typing distinguishes between two HLA antigens and gives an HLA typing result similar to a serological result (for example, HLA-A*01) (Bai et al., 2014; Madden and Chabot-Richards, 2019). This level of resolution is usually adequate for solid organ transplantation, evaluations of certain disease associations and pharmacogenomic analyzes (Madden and Chabot-Richards, 2019). In spite of the routine use of this level of resolution, an inadequate match may lead to immunological responses in the recipient and a poor transplant outcome. In contrast, more recent use of high resolution HLA typing or four-digit typing (for example, HLA-A*02:01) has greatly improved transplantation outcomes. This level of resolution is based on genetic sequencing that identifies the sequence of the peptide binding region of the HLA allele (01 in the HLA allele name in the example above) as well as the number of alleles to be determined for a given locus and the HLA alleles present in the sample (Madden and Chabot-Richards, 2019). High resolution methods can also detect variations in amino acid or polymorphisms within the HLA genetic sequence which may affect disease status or the immune response (Bai et al., 2014). This level of resolution is also required for bone marrow transplantation and is used for disease association research and pharmacogenetic testing.

Serology (Serotyping)

This was the original HLA typing method and is based on the reaction between HLA receptors and diluted blood serum antibodies to identify the specific phenotype. The sample serum containing an individual's HLA antibodies was incubated with known HLA antigens in the presence of complement. A reaction would form an immune complex precipitate that is then detected by agglutination or cytotoxicity measures (Steward, 2001; Fasano et al., 2017; Madden and Chabot-Richards, 2019). A positive reaction would indicate binding between the antigen and antibody. The degree of the reaction would be determined for each unknown by comparing it to known controls to provide a quantitative value for each reaction. This allowed for identification of individual antigens or HLA sequences based on the serum antibody binding affinity.

A number of significant disadvantages were found with this technique. False positives may occur if HLA alleles contain additional genetic sequences that encode for non-HLA proteins. These proteins may then react with the antigens present in the test and give a false positive result. Additionally, the collection and preparation of the processing and handling of the assay constituents are strongly affected by technical proficiency and could also have a direct impact on the occurrence and extent of the agglutination and cytotoxic reactions (Fasano et al., 2017). As a result, the test results have been greatly dependent on technical expertise and experience for their interpretation. All these factors cause the serological methods to be highly subjective and has led to many inaccurate HLA typing results.

Of particular concern is that the antigens used for antibody development may not be the same between manufacturers or products. One specific source of variation is whether the original antibody is natural or recombinant in origin. A natural antibody is one derived from the blood serum of individual and, therefore, may vary in strength, composition and reactivity between

individuals or the same individual over time. A recombinant antibody is manufactured in the laboratory and is typically clonal in origin so its characteristics would be the same in any situation. Additional sources of variations are due to the amounts of antibodies used in each assay; generally, the more antibody used, the greater the reactivity.

Although molecular-based testing methods are favored in many cases due to their greater resolution and typing accuracy, serological methods have continued to be used. A significant advance occurred with the development of monoclonal antibodies which allowed greater consistency in the binding reactions. New serological antibodies for HLA typing continue to be developed and, once validated, are commercially available. However, in spite of these developments, the polymorphic nature of the HLA family increases the risk of misidentification of specific alleles if only serological testing is used. In many cases, once the serological testing is completed, a genetic sequencing or a prediction method such as familial haplotype analysis is used to confirm the initial results and to provide a greater resolution for the HLA genotype.

Cellular typing

Cellular typing or mixed lymphocyte culture (MLC) cellular typing (also known as microlymphocytotoxicity typing) is used in conjunction with serological testing for identification and confirmation of the HLA type. This method is also based on the reaction between the HLA antigens and specific antisera or monoclonal antibodies. Cellular typing is considered more sensitive than serological typing in identifying HLA differences resulting from T-cell stimulation that is not detected by the serological antibodies.

Although these MLC assays are more sensitive than serological methods, they are not considered very sensitive as compared to other HLA typing techniques such as solid-phase or sequencing tests. Similar to serologic testing, the MLC results are based on agglutination or cytotoxic reactions whose interpretation is not only labor-intensive but highly subjective (Fasano et al., 2017). In addition, this method requires a relatively large number of viable, previously HLA-typed lymphocytes in order to obtain HLA specificity in the results (Tait et al., 2013). Since the cell suspensions are collected from the serum of individual donors, they may also include non-HLA antibodies which can lead to false positive results during the HLA typing test. As a result, this method is difficult to standardize and the final result is dependent upon the HLA composition of the lymphocyte panel used in testing, leading to different results from various laboratories, each using its own lymphocyte panel. These assays also cannot identify all HLA types in highly sensitized patients due to the presence of numerous HLA and non-HLA antibodies. In spite of these disadvantages, this method is still in use in many laboratories, especially those involved in organ transplantation.

For organ transplantation purposes, MLC testing has previously been used to detect any reactions between recipient lymphocytes and potential donor antigens (Hutchinson, 2001; Fasano et al., 2017). This method requires that the recipient lymphocytes be collected in sufficient volume with confidence that only the lymphocytes have been isolated. Although this concept may provide the preferred result, the test requires 4–5 days before a result is available. This timeframe is not acceptable when using organs from brain-dead donors that must be transplanted within 24–48 h. This technique, however, can be used for living donors such as those for bone marrow transplantation.

Solid-phase methods

In contrast to serological and cellular assays, solid-phase methods or bead-based assays are highly sensitive techniques used for identification of both HLA-antibodies and MHC Class I and II HLA molecules. These methods are found as commercially available kits that contain solubilized HLA sequences bound to a solid matrix, either a microtiter plate (enzyme-linked immunosorbent assay or ELISA) or polystyrene microbeads with the HLA specificity listed by the manufacturer for each kit (Reed et al., 2013; Tait et al., 2013; Gu et al., 2020). In each method, the matrix is coated with native or recombinant Class I or Class II HLA antigens to which the sample serum is added and incubated; positive results indicate binding of HLA antibodies in the sample to the specific HLA antigen in the kit (Schinstock et al., 2016; Fasano et al., 2017).

ELISA technology was initially used for these assays with the solid matrix being a microtiter-well plate. The degree of HLA-specific antibody binding in each sample was measured via optical density analysis with the test ratios compared to a known control (Steward, 2001). The HLA type would be determined by evaluation of the pattern of positive reactions. Currently, this methodology uses polystyrene micro beads as the solid phase and are fluorescence-based. Detection of the fluorescent signal is accomplished using flow cytometry with a fluorescence-activated cell sorter (FACS) and the results are expressed as the mean fluorescence intensity (MFI), a value that represents the relative fluorescence of a specific bead or combination of beads. The beads are coated with the HLA molecules and conjugated with two fluorescent probes (usually fluorescein isothiocyanate (FITC) or phycoerythrin (PE)) (Reed et al., 2013). A third reagent, a fluorescent-labeled IgG antibody, is added to the mixture as a reporter molecule for detection of any binding reactions between the antigenic HLA molecules and the sample DNA.

A distinct advantage of the fluorescent-based bead assays is that this technique may be used in multiplex arrays. These multiplex systems allow the simultaneous detection of several different antibodies so that a more detailed typing analysis may be completed in one test system, making this methodology extremely common in HLA testing laboratories (Fasano et al., 2017). A widely used example of the multiplex bead assay uses the Luminex® platform where the beads, coated with the HLA sequences, are the bound with the two fluorescent dyes (the ratios depend on the manufacturer). This process can produce up to 100 different bead populations per assay (Tait et al., 2013; Schinstock et al., 2016). Using a dual-laser flow cytometer or fluoroanalyzer, the fluorescent signal of each bead is identified by one laser while the signal of the HLA-specific antibody binding is simultaneously determined by the second laser. The Luminex® assays have a high sensitivity and can detect low levels of HLA antibodies and separating the binding affinities of each reaction into low, intermediate and high levels.

Both the ELISA and bead assays on the Luminex® system provide a semiquantitative assessment of HLA-specific antibody binding which is based on the detection limits of the technique being used (Tait et al., 2013; Reed et al., 2013). In many cases, the MFI is reported as a numerical value that has been used as a determination of HLA antibody binding capacity for both HLA typing and comparison of results between laboratories (Sullivan et al., 2017). It should be noted that, although the Luminex® bead assays are used as semiquantitative tests, this method was approved for use by the Food and Drug Administration (FDA) as qualitative assays that would deliver only a positive or negative result (Schinstock et al., 2016).

Although the solid-phase methods have a greater sensitivity than serological or cell-based methods, both the ELISA and bead assays are subject to variations due to the equipment used, manufacturers or suppliers of the kits and reagents, sources of HLA antigens, reagents and cell-to-reagent ratios. All these factors make the solid-phase assays difficult to standardize and variable results are common between laboratories (Tait et al., 2013; Fasano et al., 2017; Reed et al., 2013). Additional variability is due to the numerous kits available that have differences in the density and characteristics of the HLA molecules bound to the beads as well as different amounts and ratios of reagents used in each kit (Reed et al., 2013). The solid-phase assays also require significant expertise in their use and interpretation (Tait et al., 2013; Schinstock et al., 2016; Fasano et al., 2017). Analysis of these assay results have shown that conduct of the study itself (i.e., pipetting, bead washing, vortex speeds, centrifuging, etc.) also have a significant impact on the MFI results (Kim et al., 2019). This variability may be minimized through strict adherence to test protocols and conditions along with the use of robotic sample-handling equipment (Tait et al., 2013; Gu et al., 2020). Overall, the variability between laboratories (i.e., personnel expertise differences, laboratory temperatures, reagent characteristics such as pH, etc.) may account for 50% or more differences in the results (Kim et al., 2019).

An additional source of variability is the need to establish a cut-off concentration for each fluorescent signal for determining what is positive or negative. This is done in accordance with the manufacturer instructions and previous laboratory evaluation when the test protocol is first established and/or when new equipment or kits are being implemented. Variations in the MFI cut-off concentrations between positive and negative results can lead to significant differences in HLA typing results between laboratories, resulting in either false positives or false negatives. These situations can result in either not using an otherwise compatible organ or having a poor transplant outcome with organ rejection.

Another source of variability specific to the Luminex® assays is known as the prozone effect that may lead to false negative results (Kim et al., 2019; Gu et al., 2020). This effect occurs mostly with DNA from patients with high levels of HLA antibodies, causing a low MFI signal that is undetected by the reporter fluorescent antibodies and producing a false negative result. The prozone effect is caused by the C1 complement component protein or other molecules including IgM antibodies, medically-administered immunoglobulins and naturally-occurring immune complexes. These proteins or molecules reduce the intensity of the fluorescence by interfering with binding of the serum HLA antibodies to the fluorescent probe coated on the bead surface or with the fluorescent signal of the detection agent itself (Schinstock et al., 2016; Gu et al., 2020). Treatment of the sample serum with ethylenediaminetetraacetic acid (EDTA) or dithiothreitol (DTT) or other techniques such as preheating or diluting the serum has been used to reduce the prozone effect but this is typically done on a case-by-case basis (Kim et al., 2019). EDTA is the primary treatment option and has been used due to its iron-chelating properties that inhibits formation and promotes dissociation of the C1 complement complex and other complement degradation products. Similar results were found with DTT treatment. Although recommended for reducing the prozone effects, EDTA or DTT treatment is not part of the standard protocol in conducting bead assays and, as a result, no verified standard method exists for this treatment and different protocols are used in different laboratories (Kim et al., 2019).

Molecular or genetic-based methods

The great diversity within the HLA system has resulted in the reported HLA types being considered ambiguous when tested by previous typing methods. For many applications, the less sensitive and low resolution phenotypic methods are being replaced by those based on genetics to determine the exact genotype and a more accurate HLA typing result. The genetic sequencing assays use a specific sequence to determine the antibody or antigen reactivity found in the binding regions sequences for HLA Class I genes (exons 2 and 3) and for HLA Class II genes (exon 2) (Fasano et al., 2017; Madden and Chabot-Richards, 2019). Many of these methods focus on identifying polymorphisms within the Class I HLA genes since variations in the protein binding and antigen-presenting region of the HLA allele can be of significant relevance for ensuring a proper identification is made. In many countries, molecular methods are required for both donors and recipients for solid organ transplantation (Madden and Chabot-Richards, 2019). This requirement is based on the need for the accurate donor and recipient typing to minimize the occurrence of HLA mismatch and reduce the risk of transplant rejection. Knowledge of the HLA genotypes also aids in monitoring for post-transplant complications. Many laboratories that employ sequence-based HLA typing have eliminated serological-based typing methods and use multiple molecular methods. Which has led to the use of molecular methods for sequencing HLA alleles for greater accuracy, to resolve uncertain results and to identify new HLA alleles (Fasano et al., 2017; Madden and Chabot-Richards, 2019).

This category of methodology uses polymerase chain reaction (PCR) to amplify the DNA of an individual to determine their HLA genotype. The genetic sequences of the PCR probes or primer pairs are known and are designed to hybridize with single HLA alleles or families of similar alleles, providing DNA amplification of the specific HLA genetic sequences. The reference sequences for all HLA genetic typing, regardless of method, are found in a publicly available, central and curated repository, the IPD-IMGT/HLA database, a module within the greater Immuno Polymorphism Database (IPD) that contains the locus-specific genetic sequences for known HLA genes (Robinson et al., 2015). This database of HLA genetic sequences is updated every 3 months with most recent

public information on all WHO-names HLA alleles (Robinson et al., 2015; Klasberg et al., 2019). Such a comprehensive database with the most current HLA sequences that is available and searchable is critical for successful outcomes in transplantation.

PCR sequence-specific oligonucleotide probe (PCR-SSO) method

The PCR-SSO method uses PCR primers with genetic sequences complementary to a limited number of specific HLA alleles and is typically used with a solid matrix such as polystyrene beads or a microwell plate are coated with the primers (Fasano et al., 2017; Madden and Chabot-Richards, 2019). The sample DNA is first amplified by PCR and the PCR products then are added to matrix coated with the SSO primers. Detection of binding to the primer sequences may be via colorimetric or fluorescent techniques; if fluorescent, the primers are conjugated with a fluorescent molecule for detection via flow cytometry, typically a biotin derivative (biotinylation). A flow cytometer or analyzer is used to visualize the pattern of the fluorescent reactions (the pattern of bound and unbound probes). This pattern is then compared to known patterns of published HLA genetic sequences to determine the HLA genotype.

A number of commercially available kits for SSO HLA typing are available with hundreds of probes for many HLA alleles, providing a greater resolution than prior tests although the SSO results are considered intermediate resolution. A distinct advantage is that SO typing may be used for single as well as large batch testing, all within a short timeframe. However, this methodology requires using at least 100 beads for each sample as reduction in the bead count may cause the results to be invalid. In addition, a significant difference in intensity of the fluorescent signals between the positive and negative controls must be established to ensure the validity of the assay with each laboratory having its own cut-off concentrations based on their experience and the kit manufacturer recommendations.

Although SSO technology has proven useful in HLA typing identification, this method has a number of disadvantages. One such concern is that this method frequently contains allelic ambiguities. These ambiguities are partially resolved by using the “HD procedure” which uses additional or specialty probes that can hybridize to single DNA polymorphisms. Polymorphisms can then be identified and their presence included in determination of an individual HLA genotype. Non-specific binding is also a concern and may be minimized through strict adherence to washing protocols during conduct of the test. SSO primers have a shorter nucleotide length which makes identification of HLA alleles outside the primer sequence unlikely. This is especially true for those alleles that are less common or poorly documented. Additional testing by a different methodology would be required to identify these types of alleles.

Polymerase chain reaction-based sequence-specific primers (PCR-SSP) method

The SSP method is similar to the SSO method in that SSP uses PCR primers specific for genetic sequences alleles in certain HLA alleles but are highly accurate and are frequently used to distinguish HLA genotypes in cases where other methods provided ambiguous results (Madden and Chabot-Richards, 2019). For SSP testing, the sample DNA is added to a commercially available tray containing the primers to obtain the final PCR products; the target sequence is only amplified if present (Fasano et al., 2017; Madden and Chabot-Richards, 2019). These molecules are then separated by size gel electrophoresis and stained with ethidium bromide or SYBR green for visualization. The resulting band patterns show the presence or absence of specific HLA allele amplification and provide identification of the HLA genotype.

This accuracy is obtained by using only the target primers as well as a greater number of PCR cycles. The increased number of cycles generates a larger amount of product which aids in visualization following the separation step and, ultimately, increases the precision of the HLA determination. One downside to the increased number of PCR cycles means that this method is not as easily adapted for simultaneous large-batch testing. SSP testing also has greater variability due to generation of products that cause nonspecific as well as lack of binding; both conditions result in ambiguous or erroneous results. Technical expertise is also required to have accurate evaluations since interpretation of the test materials and the final HLA genotype determination depends on the presence of the clear visibility of certain sized amplicons.

More recently, detection of the binding reactions is completed using real-time PCR with fluorescently-labeled SSP primers. Real-time PCR reduces sources of contamination as can be found with gel-based manipulation (Madden and Chabot-Richards, 2019). In addition, real-time PCR tests can be completed in the shortest amount of time, can be automated and is very good at distinguishing HLA alleles.

Notably, the SSP method may result in missing some HLA alleles or even whole loci due to the use of known HLA sequences for generation of the primers. Previously unknown HLA variants may not be included in the primer sequences so the typing results for individuals with these less common alleles may appear to be ambiguous. This circumstance is not as prevalent in populations that have been largely HLA-types such as in the United States, Europe and Japan. However, other areas such as in the developing world, SSP is not appropriate for HLA gene resolution since the HLA type for a large portion of the population is unknown.

Sequencing-based typing (SBT)

SBT provides the highest resolution and is considered the best method to identify definitive Class I and II HLA alleles (Fasano et al., 2017; Madden and Chabot-Richards, 2019). This method uses nucleic acid sequencing of the exact genetic sequence in the desired DNA region so it is possible to identify HLA specific areas or alleles. Using these methods, genetic regions may be analyzed that are not covered under routine HLA typing methods, thereby detecting previously unknown HLA alleles. Sequencing also helps to eliminate the need for additional testing or cross-referencing results from other methods for HLA identification (Mayor et al., 2015).

The initial step in all SBT methods is PCR amplification of the DNA sample to ensure an adequate amount for sequencing. The primers may be generic for the majority of HLA alleles of a certain locus or specific for a limited number of particular HLA alleles. The PCR product is then sequenced using either Sanger sequencing or next-generation sequencing (NGS).

Sanger sequencing

SBT methods originally used Sanger sequencing for analysis of the PCR product to determine its genetic sequence. Sanger sequencing is a chain termination method used to determine a single nucleotide sequence from the sample DNA (Madden and Chabot-Richards, 2019). Determination of the exact sequence is accomplished using selective incorporation of a dideoxynucleotide into the chain during PCR amplification to stop the reaction. Dideoxynucleotides are known as “chain-terminating nucleotides”; these nucleotides lack a 3′ hydroxyl group which inhibits DNA polymerase, thus ending the chain elongation during protein synthesis. The final product sequences were first visualized through incorporation of a fluorescent dye by the dideoxynucleotide but now HLA typing is completed using sequencer software for genetic sequence analysis and identification. The final sequence is compared to a library of HLA allele sequence data contained in the software. Sanger sequencing allows for high resolution (4-digit results) that can identify the entire sequence across HLA alleles and include polymorphisms.

Although a number of kits are commercially available for Class I and II HLA typing via Sanger sequencing, this technique is not very scalable and a limited number of samples can be processed at any one time (Madden and Chabot-Richards, 2019). Typically, one sample at a time is done. In addition, this method is time-consuming and there is a long turn-around time. In addition, Sanger sequencing may be affected by technical issues such as the intensity of the fluorescent signals of the primers in the kits or different interpretation of the genetic analysis by various individuals and/or software. This is especially true for PCR products in low quantities which may be confused with the background signal. In these cases, where this difference between the signals is considered too small for verification purposes, the Sanger sequencing typing analysis would be considered unreliable and must be repeated. Any ambiguous results would require additional HLA typing by either SSP or SSO methods.

Next-generation sequencing methods (NGS)

Continued development of SBT methods lead to the creation of what is known as next-generation sequencing (NGS) methods. NGS are parallel sequencing methods where separate sequencing of multiple strands of DNA within a sample take place and each strand is amplified separately as opposed to all together as with other sequencing technologies (Klasberg et al., 2019; Madden and Chabot-Richards, 2019). The result are longer PCR products or amplicons for each DNA strand. This helps to reduce or eliminate many of the ambiguities or unknowns associated with other sequencing methods. The final result is the complete characterization of a double-stranded HLA allele containing both parental contributions and highly accurate HLA typing.

Currently, a long-amplicon approach is used for NGS where the entire sequence for an HLA allele is conducted via fragmentation of the sequence into smaller sections which are then amplified and combined to form the entire gene. Previous sequencing methods generated short sequences (<3 kb) that required manual overlapping of multiple fragments to form the genetic sequence of an entire HLA gene (Mayor et al., 2015). This process may result in incorrect alignment of the genetic sections with an incorrect identification of the HLA allele. This would be especially true if polymorphisms or other variations in the sequences are present. The solution, as found in the NGS methods, is the generation of longer sequences that encompass the entire HLA gene (i.e., introns, exons, and upstream and downstream regions) to resolve the presence of polymorphisms (Hosomichi et al., 2015; Mayor et al., 2015). In this way, the entire HLA genetic region can be sequenced in one high-throughput and high-resolution reaction.

A number of NGS platforms are available that use different sequencing methods for HLA typing. In general, PCR is used to determine all or almost all sequences in an HLA allele in the sample DNA. This sequencing includes additional areas such as nearby intronic and untranslated regions that may contain relevant but unidentified polymorphisms (Liu et al. 1999). These sequences are then enzymatically fragmented into smaller sections and each individual section is sequenced. Since NGS methods generate sequences from each single strand of the sample DNA, the specific sequences of paternal and maternal alleles may also be identified. NGS-generated results also have significant reductions in the ambiguity associated with Sanger sequencing with more accurate HLA typing (Liu et al., 1999). The NGS process of separate DNA strand amplification with sequencing a longer PCR product has significantly minimized the ambiguity associated with Sanger sequencing. This reduction has been recently demonstrated where a 3.5-fold reduction was found in the HLA genotyping error rate using NGS methods as compared to Sanger sequencing (Klasberg et al., 2019).

The development of these methods was driven by the need to increase both the accuracy of HLA typing for matching and the length of the allelic sequences used in this process while reducing the testing cost per sample (Robinson et al., 2015). A major advantage of NGS is its ability to provide simultaneous testing of multiple samples (multiplex testing) in a high-throughput manner as well as multiplexing (Liu et al., 1999; Klasberg et al., 2019). These characteristics allow a more efficient operation which lowers the cost per sample for HLA typing. Initially, this method may have a long turn-around time due to lack of experience with the analysis and testing procedure and the required instrumentation and software purchases are expensive. However, once established, this method provides high resolution, highly reproducible and efficient HLA typing.

Recent development of NGS sequencing methods have tested using non-PCR based system known as targeted resequencing for HLA typing (Hosomichi et al., 2015). Targeted resequencing uses biotinylated DNA primers for specific HLA genes which are incubated with known HLA genetic sequences found in the DNA library. Any hybridized or bound primers are then collected using streptavidin magnetic beads and the binding reactions visualized with fluorescent detection. The pattern of binding reactions is

compared to known sequences to determine the HLA type. Previous studies have shown that this method can be automated and used for both larger genetic regions and a greater number of HLA genes as compared to PCR-based sequencing (Hosomichi et al., 2015).

The large amount and complexity of data generated by NGS methods can be a major disadvantage in their routine use for HLA typing. High-volume laboratories such as stem cell registries routinely use these sequencing methods for HLA typing. Smaller laboratories or those that do not perform HLA typing on a routine basis may find it difficult to replace their current methodology with NGS techniques. In all cases, NGS methods generate an enormous amount of complex data and the resulting analysis requires both significant computing resources and technical proficiency. As a result, these methods may not be in place in many facilities.

Conclusion

In theory, complete HLA matching would provide a successful transplant outcome. However, this concept is impossible in practice due to the extremely high diversity of the HLA allelic family. The MHC Class I and II molecules are the most immunogenic antigens that are recognized during rejection of an allogeneic transplant. The strongest determinant of outcome is the HLA-DR status, followed by the HLA-A and -B status. Polymorphisms are known to occur in all the “original” HLA genes: HLA-A, -B and -C (Class I) and HLA-DRB1, -DQB1 and -DPB1 (Class II) (Mayor et al., 2015). Previous studies have shown that favorable organ survival occurred when the HLA Class II antigens, especially the DR antigens, are matched since the DR group is known to activate the recipient T-helper lymphocyte response (Hutchinson, 2001).

Regardless of what method is used, the “gold standard” for HLA matching is either an 8/8 or 10/10 HLA allelic match (i.e., HLA-A, -B, -C, -DRB1, and -DQB1 matched) (Lee et al., 2007). Any type of testing must identify all HLA alleles present in the sample where the method is more broad-based as with the serological techniques or more specific as with the DNA-based methodologies. The overall goal is to have HLA typing results that are accurate and reliable regardless of the method or laboratory used with the greatest amount of resolution and specificity.

Introduction

A blood type named (Blood group) is a classification of blood type depended on the availability of inherited antigenic that form from proteins, carbohydrate, glycoprotein or glycolipid, based on the blood group system on the surface of individual red blood cells (RBCs). ABO is very important in transfusion medicine. It is the only system in which the mutual immunoglobulins (antibodies) are impartially present in the sera of normal persons. In case of transfusion of ABO-incompatible blood, these immunoglobulins lead to acute hemolysis and its reaction.

O and A groups are mostly present in population globally. The plasma used in intravenous immunoglobulin induction comes from donors who have these blood O and A groups, while B and AB groups donors are fewer. ABO antibodies are clinically very important, thus, cross-matching is necessarily made at the blood bank to ensure that blood of the correct group and subgroups are transfused into recipients to prevent any major mismatch or major incompatibility that can lead to serious morbidity and mostly death (Branch, 2015). Each group has its immunoglobulins in the plasma. The associated anti-A and anti-B antibodies are usually IgM antibodies (Capolunghi et al., 2013), produced in the first years of life by sensitization to environmental substances such as food, bacteria, and viruses, namely, the I^A allele gives type A, I^B gives type B, and i gives type O. As both I^A and I^B are dominant over i , only ii people have type O blood (Yazer et al., 2006). ABO blood types are also present in other primates. RBC's surface antigens are produced by one group of carefully connected genes called allele, which jointly composes the blood group system (Landsteiner, 1900). Additional subgroups are also found, the essential subgroups of A are A1 and A2. About 80% of group A or group AB people own RBCs which agglutinates with anti-A1, so they are typed as A1 or A1B, while the remaining 20% their RBCs agglutinates with anti-A but not with anti-A1 are classified as A2 or A2B. Anti-A1 occurs as an alloantibody of 1–8% of A2 individuals' serum and 22–35% of A2B individuals (Beattie, 1972). Anti-A1 may lead to inconsistency in ABO tests and genetic incompatibility and does not match with A1 or A1B antigens on RBCs. Antigen A subgroups are more common than antigen B subgroups. The serotyping of RBCs blood groups is an immunological-based concept and foundation of inheritance. In 2019, Krog et al. designed 35 competitive allele-specific polymerase chain reaction (PCR) assays for genotyping as a molecular test of blood donors. The phenotypes have been compared with 16,119 serologic phenotypes and reported 62 contradictions, in which 43 were a result of serology. The accuracy of genotyping increased to 99.9% when contradictions caused by serology were excluded. Three of the 17 contradictions that arise as a result of genotype are due to incorrect antigen-negative prediction. Genotyping is a more powerful and highly sensitive blood group determination method than a single serotyping test and also more cost-efficient than previous technologies (Krog et al., 2019). If the serological test was done only for blood-group typing, there is a high risk caused by misjudgment of the

blood group and ABO-mismatching during transplantation. Enhancement of accurate detection of ABO genotyping is critical for successful transplantation of organs particularly kidney (Zhou et al., 2020). In the following sections, other uncommon blood groups such as the MNS blood group system, Lutheran antigens, Kell blood group system and Duffy blood group system, as well as serological and genotypic determination methods will be discussed.

Common serotyping for RBCs ABO group

It is an old and classic blood groups typing. The use of reagent A1 and B RBCs are used to reveal anti-A and anti-B in serum is named serum or the reverse test as routine blood group detection on donors and recipient must include both blood RBCs and serum tests (Code of federal regulations, 1992). Test of ABO on RBCs, or blood of infants smaller than 4 months old only is allowable to confirm the ABO type of donor units that have already been classified. The test of ABO grouping can be applied on tube, slide, gel cassettes/ cards or microplate. Some ABO RBC grouping reagents are composed from pools of sera from group of persons who their A or B blood group antigen are stimulated to form antibodies with high titer. While other ABO typing reagents are prepared by monoclonal antibodies produced by cell lines culture. Both types of these reagents are able to agglutinate directly once contacting most antigen-positive RBCs, with or without centrifugation. There is a very weak agglutination by Anti-A and anti-B in the serum with RBCs of most recipients and donors without centrifugation, so tube, column agglutination technique or microplate techniques are suitable for reaction while slide is not recommended.

Rh blood group

First studied in the Rhesus monkeys. Unlike the ABO antigens, these non-glycosylated proteins are only found on RBC membrane (Anstee and Tanner, 1993) and not in other tissues. There have been 49 Rh antigens identified (Agre and Cartron, 1991), among which are the antigens C, c, D, E, e which are lipoprotein in nature. The autosomal dominant character is in chromosome 1. One gene code for expression of RhD and another gene codes for expression of CcEe (McCullough, 2003). The most important of these is antigen D which has the highest antigenicity (Thakral et al., 2010). Accordingly, there are two types of Rhesus groups:

Rh +ve in which antigen D is present on RBC surface
Rh -ve in which antigen D is absent from RBC surface

The function of Rh is proposed to be a transporter of ammonium across RBC membrane and maintenance of RBC membrane integrity (Avent and Reid, 2000). Unlike the anti-A and anti-B antibodies, antibodies of the Rh system (anti-D antibodies) are of the IgG type (Calhoun and Petz, 2001) which is the smallest type that can cross the placenta from maternal side to fetal blood. Also, they are not naturally acquired after birth as in the case of ABO system. They developed only in Rh -ve subjects and never in Rh +ve subjects. Causes of development in Rh -ve subjects include:

- Blood transfusion of Rh +ve blood to Rh -ve subjects
- Delivery of Rh +ve baby a Rh -ve mother in which during labor the placenta separates from the uterus resulting in bleeding and entrance of some fetal blood in maternal circulation.

Concerning the donors, Rh +ve subjects do not have anti-D antibodies. They can receive blood from Rh +ve and Rh -ve subjects. Rh -ve subjects do not have anti-D antibodies unless they receive Rh +ve blood. Therefore, they should receive Rh -ve blood only. During emergencies, Rh -ve blood is not always available, that is why Rh -ve subjects may receive Rh +ve blood for the first time. This induces formation of anti-D antibodies in his plasma within 3 days after the transfusion. Therefore, any future transfusion of Rh +ve blood is contra-indicated because it will precipitate severe reaction (Flegel, 2007).

The frequency of Rh -ve phenotype differs significantly between populations and geographical and ethnical locations. It is 29% in Saudi Arabia (Eweidah et al., 2011), 15–17% in USA and Europe (Frances, 2002; Garratty et al., 2004), 6% in Africa (Olugbemi et al., 2013), and less than 1% in China (Shao et al., 2002), Japan (Ikin and Mourant, 1962), and rarer in other parts of Asia (Makroo et al., 2014). It is worthy of mentioning that platelets also express ABO group antigens and could be collected in serum. Platelet carries fragments of RBC which includes Rh, so platelets can express RhD blood group (Dunbar, 2020). Fig. 1 shows all types of blood group.

Other blood groups

There are about 36 blood group systems with more than 300 known variants. These are all classified by the “antigens” found on the surface of the red blood cells. Some include the ABO and Rh systems, and some do not meet the International Society of Blood Transfusion definition of human blood group system like Knops, Er and Vel blood systems (Harmening, 2012). Among those that considered to be of significant importance are:

Fig. 1 Blood group types classified by antigens on RBCs and platelets. ABO (classic blood group typing used to reveal antigen-A and antigen-B), Rh (studied first in the Rhesus monkey, 49 Rh antigens have been identified, antigen D is the most important, MNS (Antigens M, N and S are the most common in this group), Kell (K, k antigens), Lutheran (Lutheran glycoproteins act as erythrocyte receptors, Kidd (also known as JK antigen), Duffy (six known Fya antigens)).

The MNS blood group system

MNS blood group “M, N and S antigens are loaded on glycoporphins on the membrane of RBC membrane”. One end of a glycoporphin is connected to the underlying membrane of RBC, while the second end endures the sugars and defines type of an individual’s MNS blood. Antibody type of MNS group are IgG and IgM (Dean and Dean, 2005) Frequency of MNS antigens and phenotypes are mainly in Caucasians and Blacks. The MNS blood group system is second only to the Rh blood group system in its complexity. Many alloantibodies to antigens in the MNS system are not generally clinically significant although antibodies to low-prevalence and high-prevalence MNS antigens have caused hemolytic disease of the fetus and newborn (Palacajornsuk, 2006).

The Kell blood group system

This is complex group and contains many antigens that are highly immunogenic. These antigens are the third most potent, after those of the ABO and Rh blood groups, at triggering an immune reaction. Antibodies that target Kell antigens can cause transfusion reactions and hemolytic disease of the newborn (HDN). The k antigen is more common than the K antigen in most populations, the K-k+ phenotype is found in 98% of Blacks and 91% of Caucasians (Reid and Lomas-Francis, 2004).

The Lutheran antigens

These are recently characterized glycoproteins in which the extracellular region contains five immunoglobulins like domains, suggesting some recognition function. It has been suggested that the Lutheran glycoproteins (Lu gps) act as erythrocyte receptors for soluble laminin (El Nemer et al., 1998).

The Kidd blood group system

This system is a glycoprotein that has been recognized as clinically important in RBC serology since its identification in 1951. The JK protein is expressed on RBCs and in the endothelium of the descending vasa recta and epithelial surfaces of the kidney inner medulla (Xu et al., 1997). In renal function, this transporter protein is important in regulating urea as part of the mechanism for urine concentration and water conservation (Sands et al., 1997). The erythrocyte JK glycoprotein serves to facilitate rapid urea transport across the RBC membrane (Macey and Yousef, 1988).

Discoveries have expanded the system to include 23 variant alleles recognized by the International Society of Blood Transfusion that silence the protein expression and 7 variant alleles presumably producing weak or partial JK antigens (Hamilton, 2015). A study conducted in 2019, on Kidd blood group found that among 30 blood samples, 4 were determined serologically as Jk(a+(w)) and genotypically determined as heterozygous for the JK*01W.01 allele. While the other 26 sample have been revealed to be Jk(null) with JK*02N.01 as the most frequent allele. JK*B weak alleles were not revealed, but 3 were detected as fake positives in the tube method. While Gel card resulted in high accuracy for Jk(b) determination but couldn’t reach regular detection for weak Jk(a). So, for better method, combining both the tube and gel card methods in serology, in addition to genetic testing, this excluded the misinterpreting weak Jk(a) expression (Wu et al., 2019).

The Duffy blood group system

The system ISBT number 008/symbol (FY) was published for the first time in 1950 when anti-Fya was identified in a suspected hemolytic transfusion reaction in hemophilic patient who received RBCs for treatment of spontaneous bleeding. There are six known antigens with four main phenotypes; Fy(a+b+), Fy(a-b+), Fy(a+b-), and Fy(a-b-) (Pogo and Chaudhuri, 2000).

Blood group genotyping

RBC antigen phenotyping is an essential component of transfusion compatibility testing. Serology has been the gold standard method, but its low productivity and chance of the risk of diagnostic intervention in specific cases shorten its utilization. Genotyping is helpful for phenotyping in those cases, revealing high results and credible alternate to serology test alone. Genotyping is specified in variable hematology and oncology patient populations. Since genotyping needs a compound testing area and gives more risk of genotype-phenotype contradiction, it is presently limited, but it acts as a helpful supplement and may finally succeed serological technique as a new gold standard. Genomics influences all medicine's fields, for transfusion medicine, DNA-based genotyping is applied as a substitutional for serological antibody-based assays to detect blood groups to match the blood from donor to recipient. Much of antigenic polymorphisms as a result of single nucleotide polymorphism variation in the related genes, and arrays of DNA target the changes validated by in comparison with serotyping (antibody-dependent typing). Testing antigens that have no serological kits is a great medical achievement to detect antibodies and get appropriate donor units to save the life (Westhoff, 2019).

Transfusion medicine genomics

The feasibility of applying next-generation sequencing (NGS) for blood group prognosis is validated by three featured methods: exome sequencing, whole genome sequencing, and PCR-based targeted NGS approaches (Fig. 2). The correlation of NGS with serologic and genotyping detection was from 92% to 99%. NGS showed better detection of weak antigens, structural variation, copy number alterations, new genomic variants, and microchimerism. Transfusions of blood is a common inpatient process which suggest blood group's genomics a favorable cluster of rigor medical research in addition to requirements to foster transfusion bioinformatic defies and evaluate its clinical use (Montemayor et al., 2019).

Zhou et al. (2020) studied hundreds of uremic patients with grouping contradiction, have weak ABO subgroup alleles and 77.48% have atypical ABO antibodies. The contradiction average comparing between serotyping and genotyping was more than 40%, and the mismatching ratio of election of donor based on serotype was up to 88.74%. More than 2.5% of 356 the same patients of A blood group were estimated to be included in the weak A subgroup. In comparison with the healthy Chinese people, it was (0.53%) that is higher by serological test, but very lower than what determined in Caucasians (20%).

Importance of both techniques in transfusion medicine

The molecular antigenic base of the blood groups had been specified first in the period of 1980s–90s; it is important in medical transfusion. Molecular genotyping of blood group antigens is one of the main angles and is prosperity revealing its technique into transfusion medicine. To achieve the best way, many low to high technical methods have been improved. Based on the need of the center such as checking for level of prevalence antigens wherever antiserum is not available, emend typing of several transfused patients, examination of antigen-negative donor units to decrease the ratio of alloimmunization, etc., a good method can be selected. There is a requirement to understand this blood technology with its variances (Gorakshakar et al., 2017).

It is known about 300 RBC's antigens in addition to 33 antigens on the platelet that express difference between humans. Immune reaction against antigens is a risk complexity such as what happens in prenatal medicine and blood transfusion, especially in patients who require several transfusions such as thalassemia. Although pre-transfusion compatibility examination widely depends on serological assays, but kits are not obtainable to detect several antigens. So, assays depend on single-nucleotide polymorphism (SNP) arrays were applied but typing for ABO and Rh – the very important blood groups could not be used with SNP typing alone. So, Lane et al. (2018) developed a new assay depends on whole-genome sequencing to detect whole RBC and platelet antigens. The improved blood typing compared typing data with classic serological determination and SNP typing in three rounds of testing. It revealed the latest algorithm, which was about 99% concurrent for 200 term genomes. Applying additional and

Fig. 2 Next-generation sequencing (NGS) for blood group prognosis is validated by three featured methods

accurate antigen-matching in patients with donor's blood, antigen typing depending on whole-genome sequencing is a new method for improving transfusion results with potential transforming the pursuit of transfusion medicine.

In most of thalassemic patients, a multitransfused is common process where hemagglutination can't phenotype the blood group antigens of the patient because of the existence of donor-obtained red blood cells. DNA-based on technique can cope the restriction of hemagglutination and can be applied to define the proper antigen description of those patients which ensure antigen-matched blood for transferring to multitransfused patients, Kulkarni et al. (2018) compared the serological phenotyping with molecular genotyping of known and clinically significant antigens of Rh, Duffy, Kell, Kidd and MNS blood group systems among multi-transfused patients of thalassemia. The authors tested 200 thalassemic patients and 100 "O" group health blood donors by using regular serological technical method and polymerase chain reaction-based techniques for these antigens/alleles (C, c, D, E, e, Fya, Fyb, Jka, Jkb, K, k, M, N, S, s). They reported that genotyping and phenotyping data were inconsistent in 77% of the used patients for five pairs of paradoxical antigens of the blood group systems (Rh, Duffy, Kell and Kidd). While in the MNS blood group system, 59% of patients displayed contradiction. The ratio of alloimmunization in thalassemic was 7.5%. They concluded that molecular genotyping supported the definition of the real antigen features in multitransfused thalassemic patients which would reduce alloimmunization in those patients and helps in the better management of transfusion therapy.

High risk of blood type mismatching and genetically ABO-misidentified transplantation if serological test was carried out only in blood-group typing. Very accurate ABO genotyping is important for successful organ such as kidney transplantation as allocation of reasonable organ may lead to early graft dysfunction (Zhou et al., 2020).

Combination of both the tube technique with gel card technique in blood groups serology, along with complementary genetic assay, the probability of misinterpreting weak Jk expression has been eradicated, and the authors provided Jk null blood for securing medical transfusion (Wu et al., 2019).

ABO blood groups compatibility in human pregnant and her embryo is very critical to prevent morbidity or mortality of the fetus or new-born which are important albeit it rare but risk. When a pregnant woman has a high level of anti-A or anti-B IgG antibodies, the child may be at risk for hemolytic disease of the fetus and newborn (HDFN). Performing a direct prenatal detection of the embryonic ABO blood group can tool up good clinical data, Rieneck and his team in his recent study (2020) have created a next-generation sequencing (NGS)-based fetal ABO prognosis determination depends on a cell-free DNA analysis extracted from maternal plasma and showed its application in several samples. They can allocate a reliable fetal ABO type in about 95% of the incoming clinical samples of type O pregnant. In despite of the large genetic alterations implied in the ABO blood groups, but there are rare variants, and prenatal ABO rare and pronging is possible and provides valuable precocious notification to avoid ABO's HDFN.

Complication and risks of incompatibility of blood transfusion

The ABO reactions

Complications in ABO system occurs at 1:25,000 transfusions, mostly, due to administrative errors (Linden et al., 2000). Since 44–45% of population is of blood group O and A, it is expected that mismatch will occur due to transfusion of type A blood to type O, because type O individuals carry both anti-A and anti-B.

Acute hemolytic transfusion reactions occur when ABO-incompatible blood is transfused, resulting in recipient antibodies attaching to donor RBC antigens and forming an antigen–antibody complex. This antigen–antibody complex activates complement system, resulting in intravascular RBC lysis with release of RBC stroma and free Hb (Sazama, 1990). Immune system activation also results in bradykinin release (leading to hypotension) and mast cell activation (causing serotonin and histamine release). The net result may be a shock, renal failure due to Hb precipitation in renal tubules, and DIC (Reid and Lomas-Francis, 2003). Many signs and symptoms of an acute hemolytic transfusion reaction appear immediately and include fever, chest pain, anxiety, back pain, and dyspnea. Many are masked by general anesthesia, but clues to the diagnosis include fever, hypotension, hemoglobinuria, unexplained bleeding, or failure of HCT to increase after transfusion (Reid and Lomas-Francis, 2003). The sequence of reaction could be as follows:

Agglutination of RBCs, followed by hemolysis

In mild cases, an antigen–antibody complex forms, the main antibody in this reaction is IgM. Agglutination of RBCs may be complicated by post-transfusion jaundice. In severe reaction, a few ml of blood is sufficient to cause severe pain in the back or in the sites and tightness in the chest (due to block of capillaries by the agglutinated RBCs). This is also followed by hemolysis of the RBCs and release of hemoglobin in plasma.

Acute renal failure

Some of the intravascular hemoglobin is filtered at the glomeruli and excreted in urine (hemoglobinuria). Some precipitates in the renal tubule resulting, in addition to the low blood pressure, in acute renal failure. Acute renal failure is characterized by low urine output, high urea and high potassium ions. Death may occur in few days.

Disseminated intravascular coagulation (DIC)

In severe cases, antigen–antibody reactions may result in activation of coagulation causing DIC and therefore, fatal bleeding due consumption of the clotting factors.

The Rh reactions

Hemolytic disease of the newborn:

- Also known as erythroblastosis fetalis because the early stage of RBCs (erythroblasts) appears in fetal blood together with reticulocytes as compensation to the excessive hemolysis (Seriki, 2020).
- It occurs in Rh +ve neonate of Rh -ve mothers.
- During delivery of the first Rh +ve neonate, some of his blood enters maternal circulation. The delivered neonate is normal: but the mother forms anti-D circulation, antibodies of IgG type to get rid of the baby's RBCs (i.e., she becomes immunized)
- When she becomes pregnant again with a Rh +ve fetus, these antibodies cross the placenta, enter the fetal circulation and attack RBCs of the fetus who develops hemolytic anemia and jaundice (McCullough, 2003)
- The hemolytic anemia is associated with hyperactive bone marrow to replace the lost RBCs. The results in appearance of the early stages of RBCs in fetal blood (erythroblastosis & reticulocytotic).
- Anemia may become complicated by heart failure associated with generalized edema (hydrops fetalis) and the fetus may die in uterus.
- The jaundice is caused by unconjugated bilirubin which is insoluble in water. It may precipitate in the basal ganglia in the brain causing kernicterus (characterized by motor problems and may be associated with mental retardation) (Avent and Reid, 2000).

Conclusion

DNA-based genotyping allows the accurate prediction of multiple erythrocyte and platelet antigens by evaluating the presence of known single nucleotide polymorphisms (SNPs) and other variations. The serological methods present same limitations especially in chronically transfused patients. For example, the presence of circulating transfused RBCs/platelets with a positive direct antiglobulin test (DAT) and alloantibodies. Moreover, serological methods alone fail to identify accurately suspected variants, weak expression or null phenotype of antigens or discrepancies in blood group determination. DNA-based methods allow extensive and unbiased analysis and the identification of antigens and allelic variants. Until now, SNPs with clinical significance beyond those of the ABO and RhD systems, have been manually tested by PCR with specific oligonucleotides or using restriction enzymes or robotically by microarrays. Although these methods are robust, but being replaced by high-throughput Next-Generation Sequencing (NGS) applications. These genotyping methods decrease the risk for erroneous of ABO prediction which is of great importance in transfusion medicine.

Introduction

Inflammation is a complex defense mechanism necessary against biological, chemical, or physical threats such as infections caused by many types of microorganism, mechanical trauma, burns, ischemic necrosis, or neoplastic formations. Inflammation also plays a role in the healing process. The initiation and regulation of interactions between various components in the inflammatory process is carried out by a number of cellular and molecular events (Germolec et al., 2018; Ebersole and Cappelli, 2000).

Soluble mediators especially acute phase proteins (APPs), cytokines, and chemokines facilitate the migration of immune system cells to the injury area in an elaborately regulated chain of incidents. Acute phase changes arise immediately after beginning of infectious or destructive process. These changes are ultimately aimed to reintegrate homeostasis and removing the causative agent. These acute phase changes often sufficiently resolve the damage depending on the degree and extent of the injury (Ebersole and Cappelli, 2000; Gabay and Kushner, 1999). In contrast with the specificity of acquired immunity with humoral and cellular components, the acute phase response is not specific to identify the injurious cause (Ebersole and Cappelli, 2000).

Actually the acute phase response includes all the systemic effects of inflammation being primarily fever, hormonal changes, fluid and electrolyte imbalance, and typical alterations in protein synthesis. However, inflammation typically triggers the synthesis of certain proteins derived from liver known as "APPs." They can be detected in serum or plasma directly and are used as biomarkers for evaluating the presence, severity, and process of an inflammatory reaction or infection (Thompson et al., 1992; Germolec et al., 2018).

Continuous exposure to a stimulus or an autoimmune reaction against self-antigens can give rise to chronic inflammation. Chronic inflammation which causes fibrosis and tissue damage has been reported to have a role in pathogenic mechanisms of aging and many diseases including atherosclerosis, autoimmune diseases, asthma, arthritis, diabetes, and cancer. Serum concentrations of APPs are mostly elevated in such conditions too, although the increase is less than in the case of acute inflammation or infection (Gabay and Kushner, 1999; Jain et al., 2011). The type of inflammatory response alters according to the causing species, and severity, chronicity, and mechanisms of the inflammatory process, therewithal response and adaptation abilities of the immune system (Germolec et al., 2018).

In this article, cytokines and their role in regulating the acute phase response, classifications of the APPs, and the APPs commonly used in clinical practice will be discussed in detail.

Regulation of acute phase proteins by cytokines

Cytokines are a group of proteins which have considerable functions in inflammatory reactions. The role of cytokines is the regulation of acute-phase response with a very complex signaling network including intracellular and intercellular ways. After binding to their cell surface receptor, some cytokines trigger off or promote the response (pro-inflammatory) while others attenuate it (anti-inflammatory) (Ceciliani et al., 2002).

Cytokines are classified according to their structure or function. They function as negative or positive growth factors and pro-inflammatory or anti-inflammatory proteins. The cytokines which act as growth factor are granulocyte and macrophage colony-stimulating factor, interleukin (IL) 2, 3, 4, 7, 10, 11, and 12. The pro-inflammatory cytokines include IL-1 α/β , IL-6, IL-8, tumor necrosis factor (TNF)- α/β , macrophage inhibitory protein-1, and interferon (IFN)- α/γ . However IL-1 receptor antagonists, IL-1 binding protein, soluble IL-1 receptors, and TNF- α binding protein have anti-inflammatory activity (Khalil and Al-Humadi, 2020).

Cytokines may affect each other different ways. Many cytokines have the ability to regulate the formation of other cytokines and their receptors. Hormones, circulating receptors, cytokines, and cytokine-receptor antagonists may inhibit or increase cytokines effects on target cells. Also cytokine combinations may have additive, inhibitory, or synergistic effects (Gabay and Kushner, 1999).

IL-1 also known as human leukocytic pyrogen induces fever and comprises IL-1a and IL-1b. The cytokine family of IL-1 includes IL-1a, IL-1b, IL-18, IL-33, IL-36a, IL-36b, and IL-36g which are pro-inflammatory agonists and 4 anti-inflammatory cytokines (IL-1Ra, IL-36Ra, IL-37, and IL-38) (Akdis et al., 2016).

IL-6 is the main stimulator of the production of most APPs (Gabay and Kushner, 1999). The regulation of immune and acute phase reactions and hematopoiesis is carried out by IL-6, a multifunctional pleiotropic mediator. After IL-6 is occurred in the inflammation area, it reaches the liver via the blood flow. IL-6 stimulates production of several APPs like C-reactive protein (CRP), serum amyloid-A (SAA), haptoglobin, fibrinogen, and α 1-antichymotrypsin. However it decreases fibronectin, albumin, and transferrin productions. Transcriptional and posttranscriptional mechanisms control its expression in a strict manner. Dysregulation related to IL-6 synthesis takes a part in chronic inflammation and autoimmune conditions (Tanaka et al., 2014).

TNF- α has important roles in host defense, inflammation, and apoptosis. TNF- α maintains immune homeostasis by its pro-inflammatory, and immunosuppressive features. It shows its effects on host defense against bacterial, viral, fungal, and parasitic infections. Systemic TNF- α elevations can cause sepsis, while local increases lead to five main marks of inflammation including swelling, redness, warmth, pain, and loss of function (Akdis et al., 2016).

Serum levels of cytokines as a biomarker can also be measured in addition to APPs. There are many methods comprising diverse levels such as mRNA or intracellular protein to measure cytokine levels due to the variation of cytokine activity. Assays for cytokine measurement divided into two groups being immunoassay and bioassay. For example sandwich enzyme linked immunosorbent assay (ELISA), high performance liquid chromatography (HPLC), Meso Scale Discovery (MSD) electro-chemiluminescence, protein microarrays, and bead-based multiplex immunoassays (MIA). Multiplex immunoassays allow multiple cytokines to be measured simultaneously (Keustermans et al., 2013). On account of their very short half-life and presence of blocking factors in serum, measurement of plasma cytokine levels does not provide clinical utility (Kumar et al., 2016).

The association between cytokines and some clinical entities in inflammatory disorders has been shown. IL-6 induced arginine vasopressin (AVP) seems to be responsible for the hyponatremia and IL-6 is also responsible for thrombocytosis seen in inflammatory conditions. Cachexia, anemia of chronic disease, anorexia, lethargy and somnolence are the other associated conditions with cytokines like IL-1 beta, TNF- α , IFN γ in addition to IL-6 (Kumar et al., 2016).

The pattern of acute phase plasma markers differs in bacterial and viral infections. The elevated levels of IL-1 β and IL-6 is correlated with increased plasma CRP levels emerge in many bacterial diseases. Circulating levels of both IL-6 and CRP are detected higher in cases with bacterial enterocolitis and community-acquired bacterial infections by comparison to viral etiologies. IL-6 induced CRP levels also can be useful for discrimination of bacterial pneumonia and influenza infections and of streptococcal pharyngitis and infectious mononucleosis (Slaats et al., 2016).

Pro-inflammatory cytokine IL-18 commonly elevated in viral infections. IL-18 induces elevation of serum ferritin and Th1 immune responses through the induction of IFN- γ (Slaats et al., 2016).

Classification of acute phase proteins

The liver responds to an inflammatory process by producing a wide variety of acute phase reactants. On the other hand, the production of some other proteins is reduced. Various classifications are proposed for approximately 40 APPs that are currently known. Those that are up-regulated are called "positive APPs" and those that are down-regulated are called "negative APPs" (Cecilian et al., 2002). Additionally, another classification can be made on the basis of protein concentrations or the mechanism of action (Jain et al., 2011). Those whose concentration increases 10 to 100-folds are classified as major APPs. Serum levels of moderate APPs increase 2 to 10-folds, while those that rise less than 2 folds the normal are classified as minor APPs (Khalil and Al-Humadi, 2020). According to their mode of action, APPs are classified as coagulation proteins, complement proteins, protease inhibitors, transport proteins, and others (Jain et al., 2011) (Table 1).

Positive APPs have several physiological functions for the immune system. APPs with increased plasma levels help the immune system by recognition of invading microorganisms, mobilization of white blood cells into the blood circulation, and by directing blood flow to inflammation zones. Consequently the concentration of effector molecules enhances antimicrobial defense at locally injured or infected areas. At the same time, APPs can protect unaffected tissues from the detrimental effects of inflammation. They achieve this function by various mechanisms such as neutralizing inflammatory molecules (cytokines, proteases, antioxidants, etc.) that enter the bloodstream, minimizing the pro-inflammatory responses of leukocytes, and preventing endothelial activation (Janciauskiene et al., 2011).

Table 1 Acute phase reactants and related cytokines

Classification of APPs		Associated cytokines
Coagulation and fibrinolytic system	Fibrinogen	IL-1 β , IL-6, IL-8, TNF- α
	Plasminogen	
	Plasminogen-activator inhibitor 1	
	Protein S	
	Tissue plasminogen activator	
	Urokinase	
Complement components	Complement 3, 4, and 9	TNF α , IL-1 β , IL-6, IL-8, IL-32
	Factor B	
	C1 inhibitor	
	C4b binding protein	
Proteaz inhibitors	Mannose binding lectin	TNF α , IL-1 β , IL-6, IL-8, IL-32
	Alfa 1 protease inhibitor	
	Alfa 1 anti-chymotrypsin	
Transport proteins	Pancreatic secretory trypsin inhibitor	TNF α , IL-1 β , IFN- γ
	Ceruloplasmin	
	Haptoglobin	
	Hemopexin	
Other reactants	CRP	IL-6, IL-1 β , IL-1 α , TNF- α
	SAA	IL1 β , IL-12, IL-6, IL-8, IL-23
	Alfa 1 acid glycoprotein	TNF- α , IL-1, IL-6
	Ferritin	IL-1 β , IL-6, IL-10, and TNF- α
	Fibronectin	
	Angiotensinogen	
Negative APPs	Albumin	TNF α , IL-6
	Transferrin	IL-1, IL-6, TNF α
	Transthyretin	IL-1, IL-6, TNF α
	α 2-HS glycoprotein	
	α -fetoprotein	
	Thyroxine-binding globulin	
	Insulin-like growth factor I	
	Factor XII	

Abbreviations: APP(s), acute phase protein(s); CRP, C-reactive protein; IL, interleukin; SAA, serum amyloid A; TNF, tumor necrosis factor. Modified from Gabay C and Kushner I (1999) Acute-phase proteins and other systemic responses to inflammation. *The New England Journal of Medicine* **340**(6): 448–454; Khalil RH and Al-Humadi N (2020) Types of acute phase reactants and their importance in vaccination (review). *Biomedical Reports* **12**: 143–152.

APPs with decreased levels include albumin, retinol binding protein (RBP), transferrin, and transthyretin. It is not thought that they have an immune function and there are no clear explanations for the down-regulation of them. Speculation about the mechanism is that in the course of an acute phase response, essential amino acids for synthesis of the APPs are used in the synthesis of these proteins and the production of others is slowed down. Furthermore, negative APPs act as transport proteins and the level of the specific molecules they carry in plasma may be decreased throughout inflammatory reactions (Ceciliani et al., 2002; Northrop-Clewes, 2008).

Widely used acute phase proteins and their use in diagnostic protocol

C-reactive protein

CRP is one of the acute phase reactants that has been first discovered and it is used in clinical practice commonly. It got its name from the ability of precipitating the pneumococcal C polysaccharide (Chandrashekar, 2014). CRP is produced by many human cells being primarily liver hepatocytes additionally by macrophages, lymphocytes, adipocytes, endothelial, and smooth muscle cells (Sproston and Ashworth, 2018).

CRP testing has been traditionally used as an indicator of infection and cardiovascular events. However, with growing evidence, the important roles of CRP in inflammation including phagocytosis, the complement pathway, cytokine production particularly IL-6 and TNF- α , apoptosis, and nitric oxide (NO) release are better understood (Sproston and Ashworth, 2018). Serum CRP levels can increase up to 1000-fold within 48 h after the beginning of inflammation. Monitoring CRP levels are advantageous to determine infection and tissue injury and to follow up the course of chronic diseases (Wu et al., 2015).

CRP is a pattern recognition molecule that comprises five identical subunits arranged in cyclic symmetry with 206 amino acids which are non-covalently bound (Chandrashekar, 2014; Wu et al., 2015). CRP is a calcium-dependent ligand-binding plasma

protein. One side of the pentamer has a binding ligand for phosphoryl choline, a part of teichoic acids in gram-positive organisms, and for lipopolysaccharides in gram-negative organisms. The other side of the pentamer binds effector molecules such as the crystallizable antibody fragment (Fc) receptors Fc- γ RI and Fc- γ RII and C1q (Chandrashekar, 2014; Eschborn and Weitkamp, 2019). This interaction activates the classical complement pathway and eventually stimulates phagocytosis. CRP can also interact with substances that are exposed in apoptotic cells like lysophosphatidylcholine, ribonucleoproteins, chromatin, and histones (Eschborn and Weitkamp, 2019).

CRP structurally consists of two different forms, being as native pentameric CRP (pCRP) and modified or monomeric CRP (mCRP) (Wu et al., 2015). When CRP subjects to denaturing conditions in the existence of a chelating agent, pCRP can dissociate into mCRP. The transport of mCRP from circulation to various body sites is thought to be faster than pCRP (Janciauskiene et al., 2011). Differently from pCRP, mCRP presents antigenic, ligand binding, and electrophoretic reactivities. According to growing evidence mCRP may have pro-inflammatory and thrombotic properties. It has been reported that mCRP binds oxidized LDL more potent than pCRP (Wu et al., 2015; Janciauskiene et al., 2011).

CRP is the most easily measured and widely used test with a large amount of data about it. Conventional CRP tests have high detection limits in the acute-phase reactant range of 3–5 mg L⁻¹ (Kimberly et al., 2003). The advantages of the test are rapid response time and short half-life. The type of inflammation does not affect its catabolism. However, its serum level varies according to the severity of the inflammation. It typically increases to levels of 10 to 40 mg L⁻¹ in mild inflammation and some viral infections, while in bacterial infections and acute inflammation it rises to levels between 40 and 200 mg L⁻¹. CRP levels upon 300 mg L⁻¹ may be observed in major trauma and severe bacterial infection (Thompson et al., 1992).

It is well-known that CRP is associated with platelet activation in acute thrombosis and is a marker of cardiovascular risk. The significance of chronic inflammation in the development of atherosclerosis is also obvious. To assess chronic inflammation in atherosclerosis the measured serum CRP levels are significantly low compared to in acute inflammation. Hence high-sensitivity CRP (hsCRP) assays with detection limits of approximately 0.1 mg L⁻¹ were developed (Kimberly et al., 2003).

Automated platforms using nephelometry and turbidimetry are extensively used for measuring CRP in the clinical laboratories. The other commonly used test methods are fluorescence, chemiluminescence, lateral flow and electrochemical assays, sandwich immunoassays, and novel lab-on-a-chip based immunoassays (Eckschlager et al., 2019). There may be differences in the sensitivity of the tests. In a study, the performance of the turbidimetric method was evaluated in cases with non-ST elevation acute coronary syndromes. The turbidimetric and nephelometric methods compared on the same plasma samples. The turbidimetric method used in this study is based on agglutination of latex particles coated with antibody against CRP. This method measures CRP by quantifying the absorbed light. The nephelometric method is based on measuring the agglutination of particles by quantifying the scattered light. They found that the CRP values obtained from both tests showed a strong correlation with each other (Correia et al., 2003).

Concomitant occurrence of multiple inflammatory stimulus and influence of other factors reduce the specificity of CRP remarkably. The molecular mechanisms associated with the complicated effects of CRP in inflammation remain challenging.

Erythrocyte sedimentation rate

The ESR is a widespread hematology test utilized to determine an increased inflammatory response. The ESR is nonspecific for any disease; however, it can be used to monitor activity of some situations such as infections, autoimmune disease, or malignancies. It is more convenient to use ESR in combination with other tests (Alende-Castro et al., 2019; Bray et al., 2016). The ESR measures the distance that erythrocytes in a sample of anti-coagulated whole blood fall in a vertical tube in 1 h (Hashemi et al., 2015).

Red blood cells normally have negative surface charges which cause them to repel each other (Bray et al., 2016). In inflammatory conditions the number of proteins which are positively charged in the blood increase. This increase causes erythrocytes clumping and this formed structure called rouleaux formation. The special shape and structure of the erythrocytes is effective in the formation of rouleaux (Szołna-Chodór et al., 2015; Bray et al., 2016). This phenomenon was first noticed in 1897 and the measurement standards still in use today were defined in 1921 by Westergren (Bray et al., 2016). The International Council for Standardization in Haematology (Expert Panel on Blood Rheology) (1993) proposed the Westergren method as a reference method.

Many other non-inflammatory factors can influence ESR that is a non-specific test. The quality and quantity of the red blood cells such as the size, shape, and number will increase or decrease the ESR (Assasi et al., 2015). The alterations of plasma proteins especially fibrinogen and immunoglobulins are known to influence ESR. Fibrinogen causes them to aggregate rapidly by reducing the charge on the red blood cell surface. So that ESR is used to measure the amount of fibrinogen indirectly (Lapić et al., 2020).

Age and sex, pregnancy, renal function, use of medications and technical issues are the other factors influence ESR test (Assasi et al., 2015). In a cross-sectional study it is shown that the ESR was statistically significant higher in females than in males. Also the ESR remarkable increased with age regardless of gender (Alende-Castro et al., 2019). In the same study body mass index, smoking, and metabolic syndrome were positively associated with higher ESR results. However lower ESR results were detected in light alcohol drinkers compared to abstainers and individuals performing regular physical activity (Alende-Castro et al., 2019).

Although it has a low cost, it is a time-consuming test and may have some degree of error. Several new, safer and faster, automated and semi-automated methods have developed to perform the ESR with a higher precision (Hashemi et al., 2015). The ESR increases in a slower manner at the beginning of the inflammatory reaction and normalizes more slowly than that of other acute phase reactants due to the long half-life of some plasma proteins (Assasi et al., 2015; Bray et al., 2016).

Clinicians should consider the limitations of the test and the conditions that may implicate the results and utilize the test in a manner consistent with clinical practice.

Procalcitonin

Procalcitonin (PCT), the peptide precursor of calcitonin with 116-amino acid, consists of immature calcitonin, the N-terminal fragments and calcitonin carboxyl-terminus peptide 1 known as katacalcin. Its molecular weight is 14.5 kDa (Busch et al., 2020; Whicher et al., 2001).

The PCT gene calcitonin 1 (CALC-1) is located on chromosome 11. prePCT is produced by the CALC-1 gene. In the C-cells of the thyroid this undergoes proteolytic cleavage to produce PCT, which is further formed to the mature calcitonin. This is a constitutively active pathway resulting only in the secretion of calcitonin. Transcription and translation of CALC-1 gene is limited to the C-cells of thyroid and, more rarely to other neuro-endocrine cells. Interestingly, the promoter has sites not only for basal transcription factors but also for inducible inflammatory factors like NF κ B and AP-1 (Whicher et al., 2001; Samsudin and Vasikaran, 2017).

Inflammatory reaction induced by IL-6, TNF- α and IL-1 β due to bacterial infections activate together with PCT production in all parenchymal tissues (Samsudin and Vasikaran, 2017). However, the other tissues including the adipocytes, brain, kidney, lungs, spleen, pancreas, and colon cannot convert PCT to calcitonin. This eventually leads to rising of PCT serum levels. On the other hand, viral infections mainly characterized by IFN- γ activation, attenuate PCT production (Samsudin and Vasikaran, 2017; Covington et al., 2018).

Because of the characteristics of PCT, it has been used as a specific serum biomarker in differentiating bacterial and nonbacterial etiologies for several years (Busch et al., 2020; Samsudin and Vasikaran, 2017). As having a high pretest probability for bacterial infections, monitoring PCT levels periodically is beneficial to follow up resolution of infection and early cessation of anti-biotherapy (Azzini et al., 2020). In the current literature, potential benefits of PCT in antibiotic stewardship protocols have been shown (Choi and McCarthy, 2018). In the case of neutropenia and using an anti-inflammatory agent and with relation to the severity of the infection, levels remain unchanged as an advantage of the test (Choi and McCarthy, 2018).

To appoint PCT levels in human serum or plasma, current PCT assays utilize immunofluorescence techniques (Covington et al., 2018). The serum levels of PCT is typically very low in healthy individuals (<0.02 ng mL $^{-1}$). In the presence of a bacterial infection, levels of PCT begin to increase within 3–4 h and peak after 12–24 h. The peak levels can reach more than 400 times baseline (Covington et al., 2018; Taylor et al., 2017). In intensive care unit patients, serum levels of PCT higher than 2.0 ng mL $^{-1}$ are associated with a high risk for progression to severe sepsis and/or septic shock whereas serum levels of PCT less than 0.5 ng mL $^{-1}$ indicates a low risk (Covington et al., 2018). More valuable results can be obtained by making serial measurements rather than a single measurement in most situations (Samsudin and Vasikaran, 2017). Despite PCT concentrations are highest in sepsis and acute bacterial infections; it may not elevate in localized infections, such as abscess or empyema or in autoimmune situations (Covington et al., 2018).

Physiologic elevations of PCT levels in 3-day-old newborns have demonstrated. Additionally, fungal infections may also lead to an increase in serum PCT levels, but this increase is not as much as bacterial infections (Covington et al., 2018). But as an important point, PCT levels should be evaluated carefully in the existence of some comorbidity. The elevation of PCT in the absence of bacterial infection can be associated with severe trauma, severe burns, abdominal or cardiothoracic surgery, thyroid medullary carcinoma, small cell lung cancer, acute pancreatitis, prolonged or severe cardiogenic shock, cardiac arrest resuscitation, and OKT3 antibodies and antithymocyte globulin treatments. Stimulation of massive pro-inflammatory cytokine response may be the mechanism of the elevation of PCT levels (Covington et al., 2018; Choi and McCarthy, 2018).

The definition of PCT as a biomarker indicating bacterial infection is based on a study conducted in 1993. Serum concentrations of PCT were measured in 79 pediatric patients with bacterial and viral infections using a monoclonal immunoradiometric assay. In children with severe invasive bacterial infections serum PCT levels were very high compared to localized bacterial or viral infections. In these cases with normal calcitonin levels, the rapid decrease of PCT levels with anti-biotherapy and the correlation of PCT serum levels with the severity of infection were the other results of this study (Hamade and Huang, 2019).

In the current literature that is related to the diagnostic accuracy of PCT to predict blood culture positivity, it was shown that in patients who had proven bacteremia levels of PCT were remarkably higher (30.62 ng L $^{-1}$ vs. 10.47 ng L $^{-1}$; $P < .001$) than patients with no bacteremia.

Although most studies were performed on a limited number of patients, appropriate usage of PCT can direct clinical decisions. Early recognition of bacterial infections can prevent redundant procedures, and reduce the length of hospital stay. All of these features are ultimately associated with a reduction in mortality rate and cost (Taylor et al., 2017).

The advantages of PCT over CRP are a more rapid increase and earlier peak at 24 h following infection and a faster decrease following resolution of infection. In a study of Yang et al. (2019) among a total 614 febrile episodes, the rate of systemic bacterial infection episode was 99 (16.1%). Statistically, they demonstrated that levels of PCT were higher in gram-negative bacterial infections in comparison with febrile episodes originated by fungal infection and other etiology. When 273 neutropenic fever cases were evaluated, levels of PCT were statistically significantly higher in patients with bacteremia by comparison to those in non-bacteremic; whereas CRP levels did not significantly differ between these groups. They did not find any significant difference in levels of PCT or CRP between gram-negative and gram-positive bacteremias.

Serum amyloid A

Serum amyloid A (SAA) is an APP complexed to high-density lipoprotein (HDL) as an apoprotein. The molecule has the N terminal part which is hydrophobic and this part is possibly responsible for the lipid-binding features. The molecular weight is

11.4–12.5 kDa. The protein is coded by 4 SAA genes on chromosome 11p and has from 104 to 112 amino acids in humans and many other species (Salini et al., 2011). Despite pathophysiology of SAA has been studied for many years, all biologic functions and interactions of SAA proteins remain partly unexplained (Sack, 2020).

Infections and traumatic inflammation rapidly increase SAA plasma concentrations many folds. Both constitutive and acute phase SAA proteins are expressed extrahepatically. But, after cytokine induction, acute phase SAA proteins are produced in hepatocytes (Salini et al., 2011). Highly inducible acute phase SAA proteins are encoded by SAA-1 and SAA-2 genes in the course of the acute phase response. While SAA3 is a pseudogene, SAA4 encodes constitutive SAA proteins (Sun and Ye, 2016).

Functions of SAA like regulation of host defense and inflammation have shown in many studies. It has been found that SAA1 binds to the out-membrane of gram-negative bacteria, which acts as an opsonin. In addition, the SAA-opsonized bacteria are attacked by peripheral blood monocyte-derived macrophages with TNF- α and IL-10 stimuli. It was suggested that SAA1 potentially plays a substantial role in host defense against invasive gram-negative bacteria according to these findings (Sun and Ye, 2016).

Interestingly, chronically, or repeatedly elevation of SAA levels because of prolonged inflammation or other stimuli can bring about their cleavage and deposition as pathologic amyloid fibrils. This may be an explanation of secondary amyloid deposition that develops in individuals with recurrent or chronic inflammation (Sack, 2020).

Various detection methods mostly based on immunological approaches of SAA in serum have been reported. The immunonephelometric assay and immunoturbidimetric assay are full-automatic and broadly used in clinical laboratories. ELISA, radio-immunoassay, and radial immune-diffusion methods are essentially used only in research laboratories on account of radioactivity problems, being time-consuming and labor-intensive tests (Zhang et al., 2019).

Haptoglobin

Haptoglobin (Hp) is a mainly liver-derived α 2-glycoprotein with a serum level of 3–30 $\mu\text{mol L}^{-1}$. Hp serum levels rise many fold in case of inflammatory reactions and it takes 3–5 days for Hp to clear from plasma (Khalil and Al-Humadi, 2020). Although Hp is present in the serum of all mammals, the polymorphism is present only in humans. Three main Hp phenotypes have been detected using gel electrophoresis. These phenotypes, called Hp 1–1, Hp 2–1, and Hp 2–2 have different biological activities (Sadrzadeh and Bozorgmehr, 2004). Antioxidant and, antibacterial activity, inhibition of NO and prostaglandins, prevention of renal damage, promotion of angiogenesis, regulation of immune system are main physiologic functions of Hp (Sadrzadeh and Bozorgmehr, 2004). Hypohaptoglobinemia or ahaptoglobinemia are conditions characterized by a decrease or absence of Hp and are associated with serious allergies or anaphylaxis (Khalil and Al-Humadi, 2020).

Hp binds free hemoglobin (Hb) that is revealed when erythrocytes lyse within the vascular bed. Hb is highly toxic because of its heme group that has oxidative properties (Andersen et al., 2017). The noncovalent Hb-Hp complex formation eliminates Hb and its iron component. The CD163 receptors located on the surface of monocytes and macrophages recognize Hb-Hp complex and the complex is cleared from circulation by receptor-mediated endocytosis of reticuloendothelial system (Andersen et al., 2017; Khalil and Al-Humadi, 2020). Glucocorticoids, IL-6, and IL-10 induces macrophage expression of CD163 (Sadrzadeh and Bozorgmehr, 2004).

Hp has several functions in the innate and acquired immune systems. It has a regulatory role in various stages of cellular and humoral immunity and cytokine release. Hp reinforces leukocyte migration and antibody production, whereas it suppresses prostaglandin production by inhibiting cyclooxygenase and lipoxygenase activity, and T cell proliferation (Khalil and Al-Humadi, 2020).

Hp levels can be measured by various laboratory techniques. However, automated immunonephelometric and immunoturbidimetric methods are the most commonly used ones (Sadrzadeh and Bozorgmehr, 2004). Conditions associated with an elevated plasma Hp level are inflammation, trauma, burns, and tumors (Sadrzadeh and Bozorgmehr, 2004). However, in given hemolytic conditions, like malaria, sickle cell anemia, trauma and severe infections, Hp is consumed due to free Hb excess in plasma (Andersen et al., 2017). Decreased plasma Hp level is also seen in malnutrition, hepatocellular disorders, ineffective erythropoiesis, late pregnancy, and newborn infants (Sadrzadeh and Bozorgmehr, 2004).

Fibrinogen

One of the important acute phase reactant originated from liver is fibrinogen which is a soluble glycoprotein (Davidson, 2013; Kilicarslan et al., 2013). Its normal serum range is 2–4 g L⁻¹ and half-life is approximately 4 days (Davidson, 2013; Kumar et al., 2016). It is a substantial component of the common pathway of coagulation. Fibrinogen is converted into fibrin forms to form the clot when the coagulation cascade is activated (Davidson, 2013).

However, fibrinogen also increases 2 to 3-folds during inflammatory reactions, such as after injury or infection and disease with vascular damage (Davalos and Akassoglou, 2012). This causes an increase in blood viscosity and some degree of erythrocyte aggregation. Totally distinct to any coagulation function, fibrinogen has a role in the regulation of the inflammatory reaction. It can prompt a variety of immune and vascular cells after binding to them (Davidson, 2013).

Fibrinogen interacts with a wide variety of cell-surface proteins, adhesion molecules, and receptors involved in inflammatory processes. This interaction can be either directly or indirectly. Various cytokines and chemokines are released as a result of the interaction of fibrinogen and the toll-like receptor 4 (TLR-4), one of the receptors associated with the induction of macrophage activation (Davalos and Akassoglou, 2012).

The Mac-1 integrin which is found on monocytes, neutrophils and also T cells has a function in leukocyte adhesion, migration, phagocytosis, in addition to apoptosis and degranulation. The formation of cytokines IL-1 β , IL-6 and TNF- α is induced by binding of fibrinogen to the integrin receptor Mac-1 (Davidson, 2013).

Breakdown products of fibrin in the microvascular compartment, D-dimers, enhance local and systemic inflammation by impact of pro-inflammatory molecules like IL-1, IL-6 and plasminogen activator inhibitor (PAI-1) released from monocytes. This also induces production of CRP (Davidson, 2013).

The fibrinogen level increases in heart or circulatory system diseases and in stomach, breast and renal system malignancies (Kumar et al., 2016). In inflammatory diseases like rheumatoid arthritis, high fibrinogen levels may be observed (Rooney et al., 2011). Fibrinogen is also used as a disease activity marker in Familial Mediterranean fever (Kumar et al., 2016). Exogenous use of estrogen and oral contraceptives may cause high levels of fibrinogen (Kilicarslan et al., 2013).

Whereas fibrinogen levels decrease in liver diseases, bone lesions, malnutrition and some bleeding disorders, obstetric complications and traumas as well as prostate and lung cancers. Also the lack or low levels of fibrinogen may be seen in some congenital diseases like afibrinogenemia, hypofibrinogenemia and dysfibrinogenemia. Massive blood transfusion is one of the other reasons that can lead to fibrinogen decrease. Some of the drugs that may cause low levels of fibrinogen are steroids, androgens, phenobarbital, urokinase, streptokinase and valproic acid (Kilicarslan et al., 2013).

As APPs there are some disadvantages of the test such as long half-life, late rise and late decrease even after inflammation has suppressed. The stability of fibrinogen cannot be preserved in frozen plasma and preserved plasma (Kilicarslan et al., 2013; Kumar et al., 2016).

Ferritin

The French scientist Laufferger discovered ferritin in 1937, but the appearance of ferritin in human serum was documented by the development of an immuno-radiometric assay in 1972 (Wang et al., 2010). Ferritin is a soluble protein with 450 kDa molecular weight which present in all body cells as a cytosolic protein. Beyond that, it is also found in mitochondria and a nuclear form have been suggested (Wang et al., 2010; Cullis et al., 2018).

Ferritin is comprised of two subunits, termed H (heavy) and L (light). The proportion of H and L subunits depends on the tissue of origin (Cullis et al., 2018). The heart or erythrocytes are rich in H type chains and electrophoretic migration of it is heavier than L chains. L chains which is rich in a lighter subunit originated from liver and spleen (Wang et al., 2010; Cullis et al., 2018).

Although serum ferritin is widely regarded as an inflammatory biomarker, it is mainly an intracellular iron storage protein. Serum levels of ferritin are commonly measured as indicators of the iron amount. Moreover, ratio of the soluble transferrin receptor (sTfR) to log ferritin ratio (sTfR Index) presumably ensure a better prediction of iron status of body (Kell and Pretorius, 2014). The iron status and inflammatory status of the body are two independent causes that affect serum ferritin levels (Northrop-Cleaves, 2008).

Invading microorganisms need a substantial amount of iron as an essential nutrient ensuring their survival. They are equipped with different mechanisms for obtaining iron from host ferroproteins like hemoglobin, transferrin, and ferritin (Koorts and Viljoen, 2011). During infection and inflammation, to reduce the availability of iron, it is redirected to macrophages and hepatocytes by withdrawing from the circulation. The translation of ferritin is enhanced because of iron overload in these cells (Slaats et al., 2016).

Although serum ferritin level increases in answer to any infectious or inflammatory course, it also reflects total iron stores of the body. Therefore in the absence of infection, low serum ferritin levels can only reflect depleted iron stores (Northrop-Cleaves, 2008). Similarly, it can be used as a marker that reflects inflammation rather than iron status, mainly in countries where inflammatory diseases have high prevalence (Kell and Pretorius, 2014).

The transcription and translation of ferritin during acute phase response is directly stimulated by IL-1 β , IL-6, IL-10, and TNF- α . Elevated ferritin levels protect against microbial growth and oxidative damage. Ferritin has immunomodulatory activity, and functions in apoptotic processes and cellular proliferation (Wang et al., 2010; Koorts and Viljoen, 2011). Differently from bacterial pathogens, infections caused by viruses are generally characterized by raised plasma levels of IL-18 that is a pro-inflammatory cytokine, together with elevated ferritin. Epstein Barr virus, chronic hepatitis B and C, Human Immunodeficiency Virus infections have been related to elevated serum ferritin levels (Slaats et al., 2016).

Serum ferritin can be measured using immunoassays e.g., ELISA, immuno-chemiluminescence or immunoturbidimetric assay that use antibodies to either liver or spleen ferritin. Immuno-radiometric assays are now rarely used due to its safety risks. However serum ferritin values vary according to age, sex, and ethnicity (Cullis et al., 2018).

Plasma level of ferritin is affected by many other factors. Leakage from damaged cells is the possible mechanism for ferritin secretion in conditions like tissue necrosis and injury to ferritin-rich tissue. Malignancies including hepatocellular, breast, pancreatic carcinomas, and hematological malignancies, rapid erythrocyte turnover, malnutrition and surgery are the other conditions (Cullis et al., 2018; Koorts and Viljoen, 2011; Slaats et al., 2016). Another route of ferritin gets into the blood flow is by way of the classical ER/Golgi-dependent secretory pathway in the liver (Slaats et al., 2016).

Ceruloplasmin

Ceruloplasmin is synthesized by hepatocytes and activated monocyte and macrophages as an APP (Tisato et al., 2018). Physiologically, ceruloplasmin as a metal chelating protein transports and delivers copper to tissues (Tisato et al., 2018; Janciauskiene et al., 2011). Ceruloplasmin also plays an essential role in transport and metabolism of iron and consequently in erythropoiesis.

It converts Fe^{2+} to Fe^{3+} and this ferroxidase activity inhibits reactive oxygen species production that is ferrous ion-mediated (Bakhautdin et al., 2013). Ceruloplasmin also exhibits bactericidal activity. Its ferroxidase activity reduces the availability of free iron, as a consequence limits bacterial growth (Bakhautdin et al., 2013).

Ceruloplasmin exhibits relatively modest acute phase behavior (Janciauskiene et al., 2011). The plasma levels increase typically about a 50% in response to inflammation, trauma, or infection (Janciauskiene et al., 2011; Bakhautdin et al., 2013). $\text{IFN-}\gamma$ and $\text{TNF}\alpha$ induce expression of ceruloplasmin from myeloid cells (Bakhautdin et al., 2013). The potent antioxidant, bactericidal and ferroxidase activities of ceruloplasmin suggests a possible anti-inflammatory function (Bakhautdin et al., 2013).

Conclusion

Acute-phase changes including hematologic modifications, APPs, complement components, and many cytokines picture the presence and severity of inflammation. APPs and other changes can be detected by a variety of laboratory techniques and utilize as a guide to diagnosis and management. In some cases, different responses occurring in certain APPs or cytokines may provide a clue about the nature of the inflammatory process. But commonly, APPs are non-specific markers of inflammation, and the tests used should be interpreted carefully in clinical practice.

Definition

Antibody phage display is a method that utilizes phage particles as vehicles to present functional antibodies on its surface for selection. The method involves an iterative process that allows for affinity-based enrichment of target specific antibody clones from a library of diverse antibody repertoire.

Phage display

Phage display is a method designed to present a plethora of peptides and proteins on the surface of phage particles for different applications. The most commonly used phage particle for phage display is the F-specific filamentous bacteriophage (Ff) (Smith, 1985). Although there are several types of Ff ranging from f1, M13 and fd, M13 is the most common of all (Ebrahimizadeh and Rajabibazl, 2014). The physical appearance and mode of assembly of Ff are unique when compared to other bacteriophage as they do not have an archetypal head and tail structure but a filament tube like structure instead. In addition to that, they do not lyse (kill) the host cell during reproduction (Mai-Prochnow et al., 2015).

M13 bacteriophage

M13 bacteriophage was first described in 1963 from *Escherichia coli* (Hofschneider, 1963). It has a single stranded DNA genome and is classified in the family *Inoviridae*, genus *Inovirus*. M13 is classified as a member of the Ff family. This group of filamentous bacteriophages are known for infecting Gram-negative bacteria (Rakonjac et al., 2011).

M13 bacteriophage genome

The genome of Ff is a circular single stranded DNA (ssDNA) which forms an anti-parallel two-stranded helix, similar to A-DNA or B-DNA. The helix ends with two loops where one of the two loops is a 32-nucleotide hairpin called the packaging signal (PS). This PS is responsible to target the genome for phage packaging as well as initiating the Ff assembly process (Russel and Model, 1989). The M13 genome encodes for the production of 11 unique proteins that is critical for the survival of the phage particle. The phage genome has an approximately 500 nucleotide long intergenic region encompassing the viral origin of replication and complementary DNA together with the packaging signal. The 11 proteins encoded can be classified as structural and functional proteins. The structural proteins include the proteins responsible for the capsid which are pIII, pVI, pVII, pVIII and pIX. The functional proteins are responsible for the replication process (pII, pV and pX), and for virus assembly (pI, pIV and pXI). Each of the proteins are encoded by their respective genes denoted with the same numerical annotation (Mai-Prochnow et al., 2015).

There are five structural proteins where only two are main precursor proteins. The first is the major coat protein, pVIII, which contains a 23-residue signal sequence that is removed by signal peptidase following insertion into the membrane. The pVIII protein is arranged to allow the N-terminus to protrude outward to the periplasm and the C-terminus remains in the cytoplasm (Wickner, 1975). The pIII which is the product of gene III (gIII) is the second precursor protein that has an 18-residue signal sequence which is also cleaved during translocation into the membrane. Majority of the pIII is located in the periplasm including the mature N-terminus. The pIII is anchored to the inner membrane of the bacteria host via a 23-amino acid hydrophobic sequence in proximity of the C-terminus (Davis et al., 1985). There are three other capsid proteins (pVI, pVII and pIX) that are not synthesized as precursor molecules but are also membrane bound. These proteins will remain bound until they assemble into a mature phage particle (Endemann and Model, 1995).

Proteins responsible for the gene synthesis process includes gene II (gII) which encodes a 409 residues protein, pII, which is a site- and strand-specific endonuclease critical for the synthesis of the double-stranded replication intermediate and the single-stranded viral DNA (Asano et al., 1999). Gene X (gX) encodes a 111 amino acid protein at the C-terminal end of pII required for the synthesis of the single-stranded viral DNA. Gene V (gV) is expressed as a dimer and functions to bind to newly synthesized viral DNA. The attachment of the translated pV ensures the synthesized DNA is maintained in a linear antiparallel form required for assembly of the bacteriophage (Fulford and Model, 1988; Guan et al., 1995). It is estimated that approximately 1500 molecules of pV is required to cover each viral ssDNA. The synthesis of pII and pX are generally regulated during translation. To inhibit translation, another function of pV is to specifically bind to the gene II and X mRNA to inhibit translation. Inhibition is initiated when high cellular concentrations of pV is achieved. This is achieved when the level of pV exceeds the level needed to bind the newly synthesized viral DNA (Michel and Zinder, 1989).

The three proteins responsible for viral assembly are pI, pIV and pXI. Incidentally, these assembly proteins are responsible for the membrane-associated assembly of the virus particle but are not part of the virion itself (Russel, 1993). The gene IV protein is synthesized as a precursor with a 21 amino acid signal sequence found mainly in the outer membrane of an infected bacteria. Post translocation of pIV to the periplasm will result in the removal of the signal peptide. It will then integrate with the outer membrane for the formation of a cylinder composed of 14 subunits of pIV. This cylinder will allow the migration of the emerging filamentous phage from the cytoplasm to the periplasmic space (Korotkov et al., 2011; Opalka et al., 2003). Gene I encodes a 348-residue protein that is distributed along the bacterial inner membrane via an internal hydrophobic region. This permits the 253 amino acids N-terminal to remain in the cytoplasmic space and 75 amino acids of the C-terminal are expressed in the periplasm. Gene XI is encoded within gene I and transcribes a 108 residue pXI which corresponds to the C-terminal portion of pI. It is inserted in the inner membrane with the same orientation as pI. It has been proposed that the periplasmic region of pI and pXI will interact with pIV in the outer membrane to form an assembly site. This site is where the assembly of the bacteriophage occurs and exits the bacteria host (Haigh and Webster, 1999).

Structure

The structure of M13 bacteriophage much like its namesake resembles long and thin filaments. In some instances, it may be described as a worm-like structure reminiscent of a strand of rice vermicelli. M13 is estimated to be approximately 900 nm in length and 7 nm in diameter, with a mass of approximately 16.3 MDa. The bacteriophage body consist of a protein sheath encapsulating a circular ssDNA which extends the entire length of the body (Rakonjac et al., 2017).

The protein sheath consists of a landscape of approximately 2700 molecules of the major coat protein. The major coat protein pVIII is a 50 amino acid protein encoded by gene VIII (gVIII). The pVIII has mainly an α -helical structure protruding outward of the phage particle. The N-terminal end of pVIII is an acidic domain that is found exposed outside of the particle whereas the C-terminal end is basic in nature and is directed inward of the protein tube. Copies of the pVIII are able to form a stable protein tube structure as these two domains are connected by a hydrophobic sequence stabilizing the entire structure. The pVIII proteins are assembled in overlapping shingle-like array with a symmetry that is defined by a fivefold rotational axis with a twofold screw axis of pitch at 3.2 nm (Wickner, 1975).

The pVIII forms the tubular shape of the rod, however the top and bottom ends of the tube shape is closed. This is done by two pairs of separate proteins, mainly pVII with pIX at one end and pIII with pVI at the other. Approximately five copies of the 33 amino acid pVII and 32 amino acid pIX make up one end of the particle. The opposing end consist of five copies of a 406 residue pIII and 112 residue pVI proteins. The pIII and pVI end is shaped similarly to a small knob-like structure that consist of the N-terminal end of

pIII. This N-terminal end of pIII harbors information for bacteria F-pilus recognition. In addition, pIII is also responsible for the recognition of the bacterial proteins involved in the translocation of the phage DNA into the bacteria. The stability of the particle is conserved by the C-terminal end of pIII together with pVI (Rakonjac et al., 2017).

The nature of orientation by the capsid proteins allows for the formation of a hollow tube with an internal diameter of approximately 3.4 nm. It is within this confine space that the viral single stranded DNA resides in a non-base-paired antiparallel form. The DNA is positioned within the virion in such a manner that a 78 nucleotides hairpin loop will always be located at the pVII/pIX end. This hairpin end is termed as the packaging signal and is critical for bacteriophage assembly efficiency. The DNA bases are oriented in the center of the phage particles permitting the negatively charged sugar phosphate backbone of the DNA to interact with the exposed positively charged C-terminal end of pVIII. This overall charge density regulates the DNA packing in the bacteriophage (Rakonjac et al., 2017).

Life cycle

The M13 life cycle can be categorized into three main stages much like the lifecycle of most viruses. The life cycle of M13 is lysogenic where the bacteriophage invades host bacteria and co-exist within the host until mature phage particles are packaged and leaves the host cell. The three stages involved in the life cycle of M13 are infection, replication, and assembly (Rakonjac et al., 2017).

Infection

The first stage of the life cycle involves the introduction of the primary phage particle into host cells. In the context of Ff phages, the host of choice is *E. coli* with a F conjugative pilus like XL1-Blue, TG1 and HB2151. The infection process is mainly a two-step process that involves the F pilus and the bacterial TolQ, TolR and TolA proteins. Infection of *E. coli* by the Ff phages begins with the interaction of pIII on a mature phage particle with the tip of the F pilus on the host which is the primary receptor. TolQ, TolR, and TolA are integral cytoplasmic membrane proteins that forms a complex which functions as the secondary receptor for infection (Click and Webster, 1998). The TolQRA complex is part of a larger *trans*-envelope Tol-Pal complex responsible for cell division and maintenance of cell envelope integrity (Gerding et al., 2007).

The pIII plays a key role in the initial interaction with the host bacteria. The N2 domain of pIII binds to the tip of the F pilus on the host, whereas the N1 domain binds to the periplasmic domain III of TolA causing a conformational change in pIII by *cis-trans* isomerization of Pro₂₁₃ located within N2 domain. This conformational change releases the N1 domain from the N2 domain allowing the TolA binding site on the N1 domain to be accessible (Lubkowski et al., 1999). The absence of the F pilus or the N2 domain will not abrogate infection but reduces the infectivity by about 1000-fold. Although the infection process can make do without the F pilus and N2 domain, the TolQRA complex and the N1 domain are absolutely required for infection (Russel et al., 1988).

Upon F pilus interaction with the pIII domains, the phage is then brought to the bacterial surface by retraction of the pilus. This retraction process is not fully understood as it has been speculated that the retraction is a result of the polymerization-depolymerization cycles of F pilus or induced by Ff phage binding (Clarke et al., 2008). The pilus retraction allows the migration of the virion into the periplasmic space via the outer membrane to allow the N1 domain of pIII to access TolA. The collective interaction of the TolQRA complex, the pIII C-domain and the N1N2 domains will allow the phage ssDNA genome entry into the cytoplasm and integration of the major coat protein into the cell host inner membrane (Bennett and Rakonjac, 2006).

Replication

Once the phage ssDNA genome has successfully made its way into the host cytoplasmic region, the next stage of the life cycle will be initiated. The next stage of the life cycle involves the replication of the phage in the form of episomes. Phage genome replication is carried out by rolling circle amplification (RCA) where the origin of replication (ori) is at the intergenic region of about 500 nucleotides allowing single strand replication in succession. Once the positive (+) strand ssDNA penetrates into the host, the negative (−) strand is synthesized resulting in a temporary dsDNA genome. The (−) strand synthesis is primed by a short RNA primer from *E. coli* RNA polymerase that binds to the (−) strand ori followed by extension by DNA Polymerase III (Higashitani et al., 1996). This will give rise to a dsDNA genome termed as the replicative form (RF). The (+) strand replication begins at the (+) strand ori of the supercoiled RF. A strand transferase (phage protein pII) will generate a nick in the (+) strand ori with the 3'-end acting as a primer for (+) strand synthesis. The replication process will cease when pII reaches the terminator sequence of the (+) strand ori. Then the strand transferase will join the 5'- and 3' ends together for a newly synthesized (+) strand. This new (+) strand will regenerate the intact RF and release the old (+) strand (Model and Russel, 1988).

The released (+) strands at the early stages of replication will serve as templates for additional (−) strand synthesis to increase the copy number of the RF in the host to approximately 50 copies per cell. The copy number of the RF will decrease again as the infected *E. coli* undergoes divisions (Lerner and Model, 1981). The RF is also the template for viral gene transcription especially for the ssDNA-binding protein, pV. As the amount of pV accumulates in the host, the (+) strands will be diverted away from further replication by pV coating of the (+) strand. The pV will dimerize to bind two strands of circular ssDNA, forming a pV-ssDNA filament. In addition to that, pV also functions as a regulatory protein that regulates pII and pX translation and (−) strand synthesis. The (+) strand-pV filament will act as the precursor for virion assembly process (Stassen et al., 1994).

Assembly

The virion assembly process for Ff is unique where the virion proteins are aligned along the inner membrane prior to assembly of the final mature filament-like virion via a secretion-like process (Loh et al., 2019). The major coat protein (pVIII) is earmarked as the dominant protein aligned along the membrane via a very efficient process. The assembly process is initiated when the packaging signal interacts with two minor coat proteins, namely pVII and pIX, and the inner membrane assembly complex via pI. The assembly then continues with the dissociation of the pV from the ssDNA in the cytoplasmic region of the inner membrane. This is then followed by the association with pVIII at the inner membrane level until the entire ssDNA genome is covered by pVIII (Russel and Model, 1989).

As the assembly process is in effect, translocation of virion proteins from the inner membrane to the growing filament occurs. During this time, the protein-phospholipid interaction is converted to a protein-protein interaction (Park et al., 2010). As the assembly includes the ssDNA genome, the translocation process allows the DNA to serve as a guide where the major coat protein is assembled (Russel et al., 1997). When the DNA is completely surrounded with pVIII, two additional minor coat proteins (pIII and pVI) will form the terminating cap of the virion to release the phage from the cell surface (Rakonjac et al., 1999). Termination of assembly occurs when the end of the DNA is reached allowing the length of the particle to be determined by the size of the DNA. If elongation is continued in the absence of either pIII or pVI, very long unstable polyphages with multiple unit lengths of the ssDNA will be formed. The instability of polyphages suggest the role pVI and pIII plays for improved stabilization of the phage structure (Lopez and Webster, 1983; Rakonjac and Model, 1998).

Antibody

Antibodies are one of the major components in the adaptive immune system that functions to safeguard the body from invading antigens. Upon encountering antigens, B-cells will proliferate and secrete soluble antibodies for circulation in the blood and lymphatic system to surveil for harmful antigens. Diversification of the antibody genes at germline level and binding specificity shaped through clonal selection concomitantly generates a wide range of antibodies to maximize the protection from any possible foreign antigens (Hoehn et al., 2016).

Antibody structure and function

An antibody, also referred to as immunoglobulin (Ig), is typically comprised of two identical heavy chains (HC) and two identical light chains (LC) (Schroeder Jr and Cavacini, 2010). These four polypeptide chains are paired together via disulfide bonds to form a Y-shaped structure with a flexible hinge at the center (Fig. 1). The flexibility is crucial for the antibody bivalency (Thouvenin et al., 1997). Human LC is classified into kappa (κ) and lambda (λ) families. Each of the HC and LC is further broken down into the variable (V) region and constant (C) region. The V region is highly variable, containing three hypervariable sites separated by four framework regions (FR). The hypervariable sites, also known as complementarity determining regions (CDRs), accounts for the

Fig. 1 Structure of an antibody and various recombinant antibody formats. (A) Typical structure of IgG comprising two identical heavy chains (HC) and two identical light chains (LC) interconnected through disulfide bonds to form a flexible Y-shaped molecule. The V_H and V_L form the fragment variable region (Fv); Fv together with C_H1 and C_L forms the fragment antigen-binding region (Fab); C_H2 and C_H3 forms the fragment crystallizable region (Fc). (B) Some of the commonly used recombinant antibody formats, such as single chain fragment variable (scFv), single domain antibody (sdAb), Fab, single chain Fab (scFab), scFv- C_H3 and scFv-Fc.

antibody variability and specificity in antigen binding. The heavy chain variable (V_H) and light chain variable (V_L) will fold to form the fragment variable region (Fv), which is also regarded as the region responsible for specific binding to a specific epitope on a target antigen. The V_H and V_L together with the light chain constant region (C_L) and first heavy chain constant domain (C_{H1}), forms two identical arms of the “Y” which is widely known as fragment antigen-binding region (Fab) (Amzel and Poljak, 1979).

The heavy chain constant domains 2 and 3 (C_{H2} and C_{H3}) forms the fragment crystallizable (Fc) region that interacts with Fc receptors (FcR) or C1q complement components to eliminate invading antigens through antibody-dependent cellular cytotoxic (ADCC) or complement-dependent cytotoxic (CDC) mechanism (Lu et al., 2018). As opposed to the V region, the C region is relatively constant with slight variations occurring at specific sites responsible for the effector cell binding. Variations at the Fc allows for further classification of antibodies into five isotypes—IgG, IgM, IgA, IgD and IgE. Each isotype predominates at different parts of the body and plays different roles in immunity (Janeway et al., 2001).

IgG is the most abundant antibody, mainly circulating in serum. Depending on the subclasses (IgG1-4), the structure of IgG differs slightly in terms of their glycosylation, disulfide bonding and hinge structure. The structural differences ultimately determine the interaction of IgG to different FcR or to complement components. For instance, IgG1 and IgG3 binds to the C1q complement component in addition to FcγRs. IgG2 binds weakly to C1q whereas IgG4 does not engage C1q, but both binds weakly to certain FcγR (Vidarsson et al., 2014). IgM is found mainly in the extravascular space, functions primarily to agglutinate invading antigens. IgM appears in pentameric form with five monomers joined together via a J-chain (Keyt et al., 2020). IgA contains a J-chain as well and an additional secretory component that aids in secretion of IgA dimers at the mucosal layer in respiratory and gastrointestinal tracts, comprising of two subclasses—IgA1 and IgA2 (De Sousa-Pereira and Woof, 2019). IgE and IgD are the least abundant Ig in serum. IgE is mainly found on the surface of granulocytes, functions to regulate the granulocyte mediators' secretion. Level of IgE is closely related to parasitic infection and hypersensitivity responses (Sutton et al., 2019). IgD is found mainly on surface of B cells with no clear understanding of its function but it is generally postulated to play a role in B-cell development (Chen and Cerutti, 2011). Antibody isotypes can switch via a mechanism known as class switch recombination (CSR). In the event of CSR, deletion and recombination is carried out at the constant region to generate different Fc (Manis et al., 2002; Stavnezer et al., 2008). These allows for different antibody isotypes to work at different locations in the body with varying functions (Table 1).

Antibody recombinant formats

Since the antigen binding function of an antibody is mainly attributed to the variable region, a multitude of antibody fragments have been engineered to cater for different applications throughout the years. Alternative antibody fragments can be generated through chemical fragmentation or genetic modification. Chemical fragmentation involves reduction of the disulfide bonds and protease digestion such as papain and pepsin to yield Fab, F(ab')₂, Fc and pFc' from a single antibody molecule (Kinman and Pompano, 2019). However, genetic modification allows for more antibody formats to be engineered. One of the widely utilized recombinant formats is the single chain variable fragment (scFv) that is comprised of a V_H and a V_L domain, interconnected through a short flexible peptide linker (Bird et al., 1988). Many studies have successfully isolated scFv binders against a wide range of antigens (Kuhn et al., 2016). The scFv is monomeric, however, multiple scFvs can be joined together through peptide linkers of varying lengths to form multivalent diabodies, triabodies or tetrabodies resulting in molecules with a higher avidity (Hudson and Kortt, 1999). Besides that, binding pockets targeting different epitopes can be engineered into a single antibody molecule to achieve multispecific antibody fragments (Choi et al., 2013). Likewise, various combination of the V_H , V_L , C_{H1} , C_L , C_{H2} and C_{H3} has yielded a vast array of recombinant formats such as Fab (De Haard et al., 1999), scFab (Hust et al., 2007), scFv- C_{H3} (Hu et al., 1996) and scFv-Fc (Bujak et al., 2014) (Fig. 1).

Single domain antibody (sdAb) is the smallest antibody fragment containing only one variable domain. sdAb, also termed as nanobody, is derived from heavy chain antibody (hcAb) such as VHH of camelids (Hamers-Casterman et al., 1993) and VNAR of sharks (Greenberg et al., 1995). Alternatively, sdAb can also be engineered from the V_H or V_L of human or mouse IgG (Hussack et al., 2012; Ward et al., 1989). sdAb has an advantage over the conventional antibody or other recombinant antibody formats because the small size allows rapid penetration to buried sites which is not accessible to larger antibodies (Abulrob et al., 2005; Garza et al., 2017).

In general, from the perspective of production and cost, recombinant antibody fragments have the advantage in terms of their smaller size and lack of glycosylation to allow efficient *in vitro* antibody production, especially in *E. coli* (Frenzel et al., 2013). The cell permeability of the smaller antibody formats allows for better infiltration efficiency which allows deeper penetration of the cell

Table 1 Summary of the antibody isotypes and their functions.

Isotype	Predominance location	Function
IgG	Circulating in serum	Opsonize pathogens for engulfment and activate the effector mechanism (ADCC and CDC)
IgM	Extravascular space	Opsonize pathogens and activate CDC
IgA	Mucosal layer in respiratory and gastrointestinal tracts	Secreted to neutralize invading pathogens at mucosal surfaces
IgD	Surface of B-cells	Hypothesized involve in B-cell development
IgE	Surface of mast cells	Regulate mast cells mediators secretion, reflect parasitic infection and type I hypersensitivity

for therapy or immunohistochemical detection (Henry and Mackenzie, 2018). Moreover, smaller recombinant antibody fragments could also benefit phage-display antibody selection process that is driven mainly by *E. coli* cells with better expression and efficient display on the phage surface.

Antibody phage display libraries

The introduction of phage display system has led to a new chapter in antibody discovery research. Different from the traditional laborious hybridoma method with mice, robust and stable filamentous phage is utilized to display antibody fragments on the coat proteins (Smith, 1985). The core principle of antibody phage display library is built on the linkage of phenotype (protein) to genotype (phagemid). To construct antibody phage display libraries, the antibody gene is cloned into phagemid, upstream of pIII gene. The phagemid contains sequences that signal for the packaging of phage particles. During the replication and packaging, the antibody fragment is translated together with the coat protein as a fusion protein and is displayed on the phage surface anchored to the coat protein (Breitling et al., 1991). A large collection of phages, each encoding a unique antibody gene, are pooled together to form a phage display library. Various antibody formats such as scFv (Hust et al., 2011; Vaughan et al., 1996), Fab (De Haard et al., 1999) or sdAb (Davies and Riechmann, 1995; Nuttall et al., 2002) can be used for phage display library construction. The antibody genes can be obtained from various species including rodents, camelids, non-cartilaginous fishes, non-human primates, and human (Kuhn et al., 2016). Several types of antibody phage display libraries have been introduced and classified based on the source of the V genes.

Naïve antibody library

A naïve antibody library is generated from B-cells of healthy donors, or individuals with no known infection at the point of collection. The antibody genes could be retrieved from mRNA in peripheral blood mononuclear cells (PBMC), bone marrow, lymph nodes, or spleen. Upon extraction, the mRNA collected is first reverse transcribed into cDNA using oligo(dt) primers or random primers to retain the large and diverse repertoire. Following the first strand cDNA synthesis, V genes are amplified using primers designed to maximally cover all V gene families (Kügler et al., 2015; Marks et al., 1991). The design of the primer set is a critical aspect in antibody library construction to ensure good gene coverage for a diverse library repertoire (Sblattero and Bradbury, 1998) and the primer design has improved and optimized over the years (Lim et al., 2010; Pansri et al., 2009; Pasello et al., 2016). On top of that, the antibody library repertoire could be stretched further by combinatorial cloning, where the V_H gene is paired randomly with V_L gene (Lerner, 2016).

Of the five antibody isotypes, IgM is usually targeted for construction of naïve antibody library as it targets the repertoire from naïve B cells (De Haard et al., 1999; Kügler et al., 2015). The repertoire of naïve antibody libraries is large, generally between 10^9 and 10^{11} (Glanville et al., 2009; Lloyd et al., 2009). Theoretically, diversification of the six CDRs would yield an infinite number of combinations, however the repertoire of a phage display library is usually limited to 10^{10} – 10^{11} due to the transformation efficiency of *E. coli* (Almagro et al., 2019). With the large repertoire size, antibodies against an infinite number of targets are generally possible. Apart from infectious diseases and cancer targets, naïve antibody library can be used for selection of antibodies against self-antigens and toxins which would otherwise be impossible to obtain through immunization (Kuhn et al., 2016; Winter et al., 1994). Antibody from naïve antibody library might have lower affinity, however, this could be overcome through downstream refinement such as *in vitro* affinity maturation (Gram et al., 1992; Sun et al., 2019).

Immune antibody library

Immune antibody library is constructed from B-cells of immunized or infected individuals against a particular antigen of interest. Upon exposure to the antigen, *in vivo* affinity maturation and V gene hypermutation helps shape a specific repertoire against the antigen. Therefore, antibodies isolated from immune libraries generally exhibit higher affinities in the nanomolar range. Like naïve antibody libraries, the antibody genes could also be isolated from PBMC, bone marrow, lymph nodes or spleen (Chan and Lim, 2017). IgG is typically targeted for immune antibody library construction while IgA and IgE is also sometimes employed for mucosal-, parasitic- and allergy-based libraries (De Alborán et al., 1995; Hamidon et al., 2018; Laukkanen et al., 2003; Steinberger et al., 1996; Wieland et al., 2006). The required repertoire of immune antibody libraries is relatively smaller compared to naïve antibody libraries although combinatorial cloning approach could stretch the repertoire slightly (Lai and Lim, 2020). Immune antibody libraries are usually tailor-made for a specific set of antigens related to a given infection. Although isolation of binders against closely related antigens are reported (Barbas et al., 1992; Kashyap et al., 2008), immune libraries are not commonly reused for different antigens as the common perception of a skewed repertoire would mean a focused application of immune libraries.

Synthetic and semi-synthetic antibody library

A synthetic antibody library is chemically synthesized and assembled *in vitro* with the base design of the genes being done using bioinformatic analysis. The scaffolds of synthetic antibody libraries are designed to have good expression levels in *E. coli* and promotes proper folding for good solubility and antigen binding. The CDRs are randomized to mimic germline or re-arranged

V-genes (Shim, 2015). Randomization of the CDRs can be achieved through mutagenesis using degenerate codons such as NNN, NNS and NNK, where N represents all 4 nucleotide bases; S represents guanine (G) and cytosine (C); K represents G or thymine (T) (Solemani Zadeh et al., 2019). Although degenerate codons could give high diversity, the process is uncontrolled and could yield codons encoding unnatural amino acid or stop codons that disrupt the folding or translation of the antibody fragments. Another randomization approach is achieved through trinucleotide mutagenesis (TRIM) technology where trimers encoding 20 amino acids are used instead of relying on random combination of nucleotides. This allows precise manipulation on the diversification of the antibody library while avoiding stop codons or unfavorable amino acid distribution or combination that discounts the library quality (Knappik et al., 2000). The repertoire of synthetic antibody library is usually big and diverse like a naïve library, thus allowing unbiased selection for any target (Tiller et al., 2013; Weber et al., 2014).

Semi-synthetic libraries are generally libraries that consist of a combination of characteristics from both the naïve and synthetic library designs. The antibody framework region is obtained from naïve B-cells or a known antibody while at least one of the CDR, usually HCDR3, is randomized at positions responsible for antigen binding (De Wildt et al., 2000; Griffiths et al., 1994; Pini et al., 1998). Randomization of the CDR allows expansion of the repertoire diversity which could be limited by the immune system of the host. This permits the repertoire to be increased while maintaining a favorable framework for antigen binding (Hoet et al., 2005).

Antibody phage display panning process

Biopanning is the process involved in the search for specific monoclonal antibody from a large pool of phages (Parmley and Smith, 1988). The biopanning process, in general, involves repetitive rounds of immobilization, selection, elution and reamplification until a predominant antigen-binding population is enriched. Usually, three rounds of panning are required to enrich the population, but the amount can be increased or reduced depending on the nature of the antigen. After several rounds of selection and amplification, prospective clones are screened through enzyme-linked immunosorbent assay (ELISA) and identified through sequencing (Frenzel et al., 2014; Russo et al., 2018). The result of the panning process is influenced by many factors, including the type of immobilization, the concentration of the antigen, the blocking agent, the binding time, the washing stringency, and the elution method (Bradbury and Marks, 2004).

Target immobilization

At the beginning of each panning process, target immobilization is a critical step. This can either be done by physically attaching it to a solid phase or to allow the target to be in free constant flow in liquid phase. The most common approach used for target presentation is by physical immobilization to various solid phases. The immobilization of antigens on solid surfaces, such as polystyrene microtiter plate (Barbas et al., 1991), immunotube (Hust et al., 2002), microbeads (Sawyer et al., 1997), immunoassay tip (Chin et al., 2016), column matrix (Breitling et al., 1991) and nitrocellulose or PVDF membrane (Hawlisch et al., 2001) have been attempted over the years. Antigen immobilization is achieved through passive adsorption, streptavidin binding or covalent linkage, depending on the material of the surface and the characteristic of the antigen. Antigens can be in the form of proteins, peptides, or whole cells. Sometimes target antigens are coupled to streptavidin, bovine serum albumin (BSA) or other proteins to ensure proper display of the targeted epitope and increase the coating efficiency especially for smaller sized antigens such as peptides or compounds (Bradbury and Marks, 2004).

Apart from solid phase panning, solution phase panning is also done as an alternative especially in the circumstances where the binding site is blocked due to steric hindrance or conformational changes as a direct consequence to the interaction with the solid surface. Instead of immobilizing on a solid surface, the antigens are allowed to bind freely with the antibody phage particles in solution before affinity capture of the antigen-antibody phage complexes (Hawkins and Winter, 1992). To carry out solution phase panning, the antigen must bear an affinity tag such as biotin moiety for streptavidin capture (Schütte et al., 2009). This approach allows for the target antigens to remain suspended in solution for binding before it is eventually pulled down using a capture molecule.

Binding phase

After immobilization of the antigen, the phage antibody library is then added to allow affinity-based binding of the antibody to the antigen. The incubation could be carried out from an hour to overnight at temperatures ranging from 4 to 37 °C. Due to the large diversity of an antibody library, non-specific binders against background especially plastic, BSA, and streptavidin are common. The presence of these non-specific binders could impede the screening and clonal enrichment process. Blocking the surface with various blocking agents, controlling the antigen density, and changing the immobilization strategy could avoid background binders. In order to prevent the enrichment of non-specific binders, a pre-incubation of the phage antibody library is done using blocked uncoated solid phase. The blocking agents commonly used ranges from BSA, skimmed milk, gelatin or even casein. At this stage, the amount of target antigen used at each subsequent round is usually reduced gradually. The reduction of target antigen at corresponding panning rounds functions to enrich higher affinity clones as the amount of binding sites has reduced allowing competition for higher affinity clones to capture (Bradbury and Marks, 2004; Russo et al., 2018).

Wash step

After binding of the antibody phage library to the immobilized antigen, there will undoubtedly be some non-specific binders that managed to bind non-specifically with the solid phase or blocking agents. The unbound phages are then removed through a wash step. Elimination of unspecific and weak binders through multiple washing steps are deemed crucial. The wash buffer is usually supplemented with surfactants such as Tween-20 to obstruct non-specific hydrophobic interactions. As the affinity of the antibody clones from the subsequent rounds are expected to increase, the stringency in the wash cycle for each subsequent round is also increased. The stringency can be modified by manipulating the duration of the wash step or concentration of the Tween-20 used in the wash buffer. Additionally, there is also the option to supplement the wash buffer with non-specific proteins at low concentrations such as BSA to compete out the non-specific binders (Bradbury and Marks, 2004).

Elution step

Proceeding after the wash step, the remaining bound phages are released from the immobilized surface. This can be done through several approaches which includes trypsin elution, pH shift or competitive elution. Trypsin elution is carried out via enzymatic cleavage at a pre-designed trypsin cleavage site located between the antibody and the phage coat protein (Hust et al., 2011). The phage particles are then released from the solid phase intact while maintaining infectivity. On the other hand, pH shift elution is achieved through disruption of the binding using acidic glycine-HCl (Kang et al., 1991; Roberts et al., 1992) or basic triethylamine (TEA) (Marks et al., 1991). The pH shift elution process must be carried out with caution as prolonged exposure in either acidic or basic environment will cause irreversible damage to the phage particles, rendering them unable to infect. Therefore, during pH shift elution, a neutralization process is immediately done using Tris-HCl to bring the pH back to pH 7. Competitive elution is another elution strategy, accomplished by adding antigens or antibodies to compete and release the bound phage particles (Clackson et al., 1991; Meulemans et al., 1994). The final step is the rescue process where the eluted phages are then reamplified in *E. coli* with the aid of helper phage. The rescue step allows for the eluted phage to infect *E. coli* and reamplified with helper phage to produce new phage particles consisting the genotype of the eluted phage particles. This newly generated population of phage particles is then used as the starting material for the next round of the selection process. At the end of each round of panning, the eluted phage particles will consist mainly of an enriched pool of binding clones when done properly.

Positive clone selection and characterization

After several rounds of enrichment, the enrichment pattern is confirmed at polyclonal level using ELISA. When positive binding patterns are observed from the polyclonal ELISA, the polyclonal pool is then spread on agar to allow for individual clones to be selected later. At monoclonal level, single colonies are selected and evaluated via direct ELISA. The number of clones required to be screened and the success hit rate varies with the library diversity and nature of the antigen. In general, a more diverse library will have a higher chance of getting more unique positive clones with higher affinity (Teixeira and Gonzalez-Pajuelo, 2018). The positive clones at monoclonal level from the ELISA assay will then be sequenced to obtain clone identity.

Recombinant antibody applications in diagnostics

Phage display derived recombinant antibody is a promising tool for diagnostics, not only due to their high specificity and affinity, but also their batch-to-batch reproducibility and flexibility for customization. With the availability of the DNA and protein sequences, recombinant antibodies are easily subjected to flexible rapid modifications into different recombinant formats, isotypes, and subtypes (Basu et al., 2019).

A common way to adapt recombinant antibodies for diagnostic is labeling of the antibody with fluorescent dyes or enzymes like alkaline phosphatase to generate a visible or detectable signal. These conjugates are usually generated by chemical conjugation methods. A major disadvantage to chemical conjugation is the potential loss of binding affinity due to uncontrolled cross-linking at the binding site and the potential batch to batch variation generated from different conjugation protocols (Szabó et al., 2018; Vira et al., 2010). Recombinant DNA technology allows for rapid and easy fusion of the recombinant antibody to the components responsible for signal detection by genetic modification rather than random chemical conjugation. Nevertheless, the application of recombinant monoclonal antibody can be applied beyond traditional direct signal detection with protein, peptides, DNA, or nanoparticle to cater for different diagnostic platforms such as bead-based assay (Zhao et al., 2021), flow cytometry (Sashihara et al., 2009), lateral flow dipstick (Gandhi et al., 2018), microfluidics (O'Kennedy et al., 2018), molecular imaging (Cochran and Cochran, 2010), and proximity ligation assay (PLA) (Blokzijl et al., 2016).

Protein fusion

As the antibody moiety is only responsible for antigen binding, the ability to generate a responsive signal readout for diagnostic requires the addition of another component to the antibody. This can be done either by indirect signal production thru a secondary medium that interacts with the antibody (labeled secondary antibodies) or by direct signal production where the signal producing component is directly attached to the antibody.

A major convenience offered by recombinant antibody is the ability to produce antibody fusions easily by cloning the antibody gene with the gene sequence of other proteins. The resulting construct can be expressed as a fusion protein in any suitable production host. An enzyme frequently fused with recombinant antibody is alkaline phosphatase (PhoA)—an enzyme that catalyzes the phosphate substrate to yield a colorimetric readout for immunoassays, immunoblots and immunocytochemistry. Several studies have demonstrated the construction of scFv-PhoA and Fab-PhoA for direct detection of various biomarkers, toxins, and small molecules such as glycocholic acid (Cui et al., 2018), aflatoxin-B₁ (Rangnoi et al., 2011), HT-2 mycotoxins (Arola et al., 2017), clenbuterol (Liu et al., 2010), plant virus potato leafroll luteovirus (Harper et al., 1997), or receptors and antigens on cells such as *Aspergillus* (Xue et al., 2013), *Bacillus anthracis* (Wang et al., 2006), *Entamoeba histolytica* (Tachibana et al., 2004). Labeling recombinant antibodies with enzymes allows for direct detection which will expedite the diagnosis protocol while omitting the need of secondary antibody binding that could impact the assay negatively due to unspecific binding. Recombinant antibodies are also frequently fused with fluorescent proteins like green fluorescent protein (GFP) for application in ELISA, flow cytometry, cell sorting and immunohistostaining of cells and tissues (Casey et al., 2000).

Besides direct labeling with detectable components, recombinant antibodies can be fused with other protein tags such as SNAP-tag that enables coupling to other fluorophores for immunofluorescence assay. Through this way, the conjugation is controlled at a specific site with a 1:1 stoichiometry (Hussain et al., 2019).

Peptide tag

Another common set up for diagnostic assays is indirect detection of the antigen-bound recombinant antibody using a secondary antibody. This can be achieved through short peptide tags such as polyhistidine tag, Myc-tag, FLAG-tag, Spot-tag, T7-tag, and hemagglutinin (HA)-tag. These short peptide tags serve the purpose for detection in ELISA and immunoblot assay while providing additional functions such as purification and stabilization (Kabayama et al., 2020). Besides that, Avi-tag is commonly engineered to recombinant antibodies for *in vivo* biotinylation of the recombinant antibody. Harnessing the high binding affinity between biotin and streptavidin, the biotinylated antibody allows for highly sensitive immunoassays (Even-Desrumeaux et al., 2010). Biotinylated antibody also allows coupling to magnetic beads for beads assay (Zhu et al., 2014).

The introduction of site-specific labeling methods using enzymes like sortase has also allowed for easy manipulation of recombinant antibodies for site specific tagging. This was demonstrated when recombinant antibodies were cloned with the peptide acceptor motif (LPXTG) of sortase to allow covalent attachment of invertase for direct antibody detection using a glucose meter (Ismail and Lim, 2016). Engineering of short epitope tag in recombinant antibody have also been studied. scFv tagged with HIV-gp36 or -gp41 peptides have shown efficient detection of natural HIV antibodies in human serum through whole blood agglutination assay (Coia et al., 1996).

DNA hybrid

Conjugation of DNA to recombinant antibodies allows translation of the binding signal to DNA level. The detection signal can be amplified through polymerase chain reaction (immune-PCR) or rolling cycle amplification (immune-RCA). Therefore, antibody-DNA hybrid provides a more sensitive diagnostic assay (Sano et al., 1992; Wiener et al., 2020). Besides that, riding on the high specificity of both antibody binding and DNA pairing, the hybrid system allows multiplexing the diagnostic assay (Brofelth et al., 2020). Site directed conjugation of the DNA is possible for recombinant antibody through cloning of protein tags to the antibody (Kazane et al., 2012).

As DNA detection systems are a plenty, the most direct approach is to use DNA chelating dyes to capture the signal of DNA templates amplified from the bound antibodies (Malou and Raoult, 2011). Another approach to utilize antibody-DNA fusion for diagnostic is by the generation of a fusion mixture by combining biotinylated oligonucleotides with biotinylated antigen at specific ratios with streptavidin beads. This setup was used in both a direct and indirect detection system that did not require further addition of dyes or chromophores. The setup was able to carry out direct detection of the antibody as well as conduct a competitive in direct assay to determine the presence of the target antigen in the sample. The sample readout was generated by using the attached oligonucleotide comprising of DNAzyme sequences which is able to fold into G-quadruplex structures and yield the same colorimetric response as peroxidase with the addition of a suitable substrate (Omar et al., 2013).

Nanoparticle conjugate

Nanoparticles are often conjugated with antibodies due to their excellent physiochemical characteristics. One of the examples is colloidal gold nanoparticle (AuNPs). AuNPs is characterized with a bright red color when free floating in solution. Accumulation of antibody conjugated AuNPs on a spot or line coated with antigen will result in visible color. Hence this technique is extensively applied in lateral flow assay to allow rapid, point-of-care diagnostic and detection of chemical such as morphine (Gandhi et al., 2018). Besides that, photostability and the bright color of AuNPs makes gold-antibody conjugates suitable for tumor bioimaging applications (Lin et al., 2021; Qian et al., 2008).

Another class of nanoparticles is quantum-dots (QDs) and carbon-dots (CDs) which are essentially fluorescent nanoparticles. Conjugation of these nanoparticles to recombinant antibodies can be applied for fluorescent imaging of tumor for cancer diagnosis or detection of chemical via fluorescent immunoassay (Sahoo et al., 2019; Zhang et al., 2020). The use of fluorescence allows for a

higher sensitivity as well as the possibility to carry out multiplex assays in arrays for high throughput diagnosis. Carbon nanotubes (CNT) have also been used in this respect for diagnostics. Carbon nanotubes is a hollow cylindrical carbon structure with one or more walls that enables conjugation of various components, including antibodies, to create immunosensors for diseases or cancer biomarker detection (Lerner et al., 2012). The assay is directed via detection of the electrical charge changes (Kierny et al., 2012). The sheer amount of different formats, configurations and modifications afforded by recombinant antibody technology makes it ideal for diagnostic applications. These customizations allows greater freedom in designing diagnostic assays making it a useful and flexible tool to have as a diagnostic tool.

Introduction

Immunoglobulin monomers are composed of two identical heavy and two identical light, polypeptide chains linked by disulfide bonds, with an overall molecular weight of about 150 kD. The C-terminal portion of the heavy chain defines the immunoglobulin class and subclasses IgG₁₋₄, IgM, IgD, IgE, or IgA₁₋₂. The light chains are called kappa and lambda and are common to immunoglobulins of all classes. A single clone produces either lambda or kappa chains, never both.

IgG is usually found as a monomer which sediments in a density gradient at 7S, while IgM is normally found as a pentamer, 5 units about 150 kDa each, attached by disulfide bonds (with a combined molecular weight about 800,000). Pentameric IgM sediments at 19S. IgA may be found as a monomer in blood or as a dimer in secretions.

The light chains are polypeptides of about 22.5 kDa. They may exist as monomers or as dimers with a molecular weight of about 45 kD (Sølling, 1981). The dimers may be covalently disulfide-linked or non-covalently linked (Peterson and Berggard, 1971). There are about equal amounts of covalent and non-covalent dimeric kappa chain forms in normal serum, but the lambda chain dimers are mainly covalent (Sølling, 1981; Solomon and Weiss, 1987). Normally, more kappa chains are synthesized than lambda, resulting in a normal serum kappa/lambda ratio for intact Ig that is about 2. Free light chains (FLC) are produced in excess of heavy chains as a result of de novo synthesis, and normally polyclonal FLCs spill over into the serum and urine (Peterson and Berggard, 1971; Sølling, 1981).

Parts of the light chain are wrapped around (bound to) the heavy chain and amino acids in wrapped portions are not exposed at the surface. These are called hidden epitopes. For assay purposes, by unravelling the chains, antibodies can be made against both exposed and hidden epitopes. Techniques have been developed for treating a solution of such antibodies against hidden and exposed epitopes with intact Ig so that the those with activity against exposed sites are absorbed out leaving the antibodies against the hidden sites in solution. These antibodies are called antibodies against FLC only and will not react with light chains attached to the heavy chains. These antibodies can be used in assays to detect monoclonal FLCs without reacting with light chains bound to the heavy chains. Light chain antibodies developed against intact immunoglobulins will react with hidden and exposed epitopes and can be used to measure both free and bound light chains.

The immunoglobulins formed early in the process of antibody formation are IgM and IgD isotypes. Upon exposure to antigen, class switching occurs so that IgG, IgA, and IgE isotypes are produced (van Dongen and Wolvers-Tettero, 1991). This process allows for combinations of gene products giving rise to more than 5×10^7 different antibodies providing great diversity and, remarkably, antibodies can be made against all possible antigens beginning with rudimentary minimally specific antibodies and progressing by somatic mutation to highly specific antibodies (Levinson and Miller, 2002; Chiu et al., 2019). Normally immunoglobulins are polyclonal and migrate on electrophoresis as a diffuse group. Monoclonal proteins (M-proteins), also called paraproteins, migrate as a discrete band and were first observed as a protein peak or spike by optical methods in Longsworth et al. (1939). The term M-protein was coined in Moore et al. (1943).

Monoclonal gammopathies occur because of an abnormality of the immune system's B-lymphocytes or B-cells, most often a malignancy of a signal clone that produces excess immunoglobulin of one type that is either kappa or lambda. The diseases associated with M-proteins include multiple myeloma, Waldenstrom macroglobulin anemia (lymphoplasmacytic lymphoma of the bone marrow) or other non-Hodgkin's lymphomas, amyloidosis AL, cryoglobulinemia and less commonly light chain deposition disease, polynephropathy—organic megaly—endocrine and skin (POEMS) syndrome and other neurological manifestations. The normal plasma cell count in bone marrow is less than 5%. In multiple myeloma, the count is invariably greater than 10% and the cells are clonal, but in other disease associated with M-proteins, such as amyloidosis, POEMS syndrome, or cryoglobulinemia, the plasma cells are clonal but the count may be less than 10%. In these conditions, the M-protein itself or other substances related to the dysplastic cells cause the disease.

Besides, the most common manifestation is monoclonal gammopathy of unknown significance (MGUS) that may progress to myeloma over a period of years, be associated with other diseases or be benign. In some rare cases, a small amount of M-protein unassociated with monoclonal disease, may be synthesized due to stimulation of the immune system by a single antigen such as by vaccination, but usually such (a few/several) antigens cause the production of gamma globulins from several clones (oligoclonal). Such gammopathies are usually short lived (Soubrier et al., 1994).

Monoclonal gammopathies represent a proliferation of one cell type from a single germ line causing the clonal synthesis of a single type of immunoglobulin in excess of normal amounts (Attaelmannan and Levinson, 2000). Since the production of M-protein is from a single cell line, the aberrant protein is always either kappa or lambda, never both. Most often the aberrant or dysplastic cell secretes IgG, but in many cases IgM or IgA is secreted and rarely IgD or IgE. Also, in many cases, a monoclonal free light chain is secreted along with the intact immunoglobulin or less often a free light chain is secreted alone, without an intact immunoglobulin and rarely only a heavy chain is secreted—so called heavy chain disease. The monoclonal proteins are important in diagnosis and act as biomarkers so that progress of the diseases can be followed with treatments.

When in the form of a malignancy, the malignant clone suppresses normal Ig producing cells so that normal polyclonal immunoglobulin levels are low. Since polyclonal immunoglobulins represent antibodies against multiple infective organisms and the M-protein usually has no or poor immune reactivity, this leads to humeral immunodeficiency and recurrent infection. Also, the interaction between myeloma cells and the bone microenvironment ultimately causes activation of osteoclasts and suppression of osteoblasts, resulting in lytic bone lesions and hypercalcemia when there is extensive bone involvement (Terpos et al., 2018). Increased bleeding and anemia may also occur for a variety of reasons.

Some intact M-proteins cause type I cryoglobulinemia that may precipitate in small blood vessels, especially those exposed to the periphery where the temperature may be cooler (Voma and Levinson, 2016), causing severe cutaneous involvement (necrosis and ulcers); nephropathy and neuropathy (Neel et al., 2014). Type I cryoglobulinemia, or simple cryoglobulinemia, is usually due to IgM, but rarely IgG or IgA. Also, some M-proteins, especially IgM, may exhibit rheumatoid factor activity and bind to polyclonal IgG causing complexes that can precipitate in small vessels.

If a monoclonal FLC is secreted there is a high probability of renal disease since monoclonal FLC are toxic to the kidney (Levinson and Keren, 1994). Moreover, there is evidence of an association between intact M-proteins and kidney disease (Wang and Hogan, 2018) so kidney disease is common in patients with M-proteins (Tandon et al., 2018). Also, it is possible that some patients with apparent MGUS who exhibit a low level M-protein also produce a monoclonal FLC but of such low level it is undetectable by current methods. Monoclonal FLCs are also prone to cause amyloidosis AL where fibrils may precipitate in the glomerulus, heart, joints, liver and gastrointestinal track causing disease (Levinson, 2012a,b; Vaxman and Gertz, 2019). Patients with this diagnosis often do more poorly, even with apparently successful treatment. For these reasons, it is important to determine whether or not monoclonal FLCs are present by highly sensitive methods.

Generally, if a patient has vague symptoms such as anemia or back pain a monoclonal gammopathy is pretty much ruled out by performing a serum protein electrophoresis (SPE or SPEP) where a monoclonal protein is found about 80–90% of the time when there is a true monoclonal gammopathy. According to the most recent guideline of the international myeloma Working Group (IMWG) (<https://www.myeloma.org/international-myeloma-working-group-imwg-criteria-diagnosis-multiple-myeloma> Accessed 01/08/2021) which are very similar to older guidelines (Dispenzieri et al., 2009). If there is a high suspicion of monoclonal gammopathy, due to multiple symptoms such as pain in the bones, fatigue, tingling or kidney disease, recurrent infection, increased bruising, or unexplained bleeding, the combination of SPE, serum immunoelectrophoresis (IFE), and serum free light chain (SFLC) assay are recommended for initial screening. When amyloidosis AL is suspected, urine protein electrophoresis and urine IFE should be performed in addition. These symptoms are often referred to as CRAB (hypercalcemia, renal failure, anemia, and bone disease).

Methods for detection

Serum protein electrophoresis and immunofixation electrophoresis

Separation of the proteins by SPE

SPE has been performed in clinical laboratories for over 50 years and remains the main stay for M-protein screening. Serum is used rather than plasma because fibrinogen in plasma migrates in the beta-gamma region of the gel and can be mistaken for an M-protein or can mask an M-protein migrating in the same region. In some cases plasma is inadvertently poured into a serum tube and in other cases patients are highly anticoagulated so that fibrinogen is present and interferes with interpretations (Qiu et al., 2003). But follow-up testing by immune fixation electrophoresis will show it is not an M-protein. Protein electrophoresis first developed by Arne Tiselius in 1931 as moving boundary electrophoresis in a liquid for which he won the 1948 Nobel Prize in chemistry. It is based on the principle that proteins which are composed of amino acids, show charges depending on the properties of the amino acids, the configuration of the protein and the pH of the buffer and medium and will therefore migrate when subjected to an electrical field. The migration of proteins in an electric field is largely determined by the charge on the molecule, and the pH of the electrophoretic medium. Different proteins will separate from one another in accordance with the molecular charge. Electrophoresis on a media is called zone electrophoresis. In gels containing a cross-linked matrix, such as acrylamide or starch, the separation may be substantially influenced by the size of the molecules.

For serum protein electrophoresis, a media, kept at pH of greater than 8.0 by a buffer, is placed between positive and negative electrodes and the proteins placed in a well on the media migrate with the current towards the positive electrode (Ramanathan and Srinivas, 2018). After electrophoresis, the proteins in the gels are fixed with a preservative. The gels are then stained with a stain that binds to the proteins and washed to remove excess stain. For clinical laboratory use, over the years, the media has changed from paper to cellulose acetate to agarose, each improving the separation between protein fractions. The buffer has changed from liquid to liquid-solid so that pure liquid is no longer used, and the process has been automated with 50 or more samples run at one time (Fig. 1). Yet, the overall profile has remained the same—clinically described in five fractions: albumin, alpha-1-proteins,

Fig. 1 Multiple samples on one gel. In this example 80 SPE can be analyzed on one gel. The automated densitometer can then profile and print the results. The entire process can be performed in a couple of hours allowing hundreds of samples to be analyzed per day. Interpretation of 80 samples may take a few hours. Although follow-up testing by IFE may take three or four more hours only those with an M-protein needs follow-up testing. Moreover, in hospital laboratories, where patient records are available, follow-up testing is usually not needed for monitoring progress, since the nature of the M-protein can be determined from the record.

alpha-2-proteins, beta-proteins and gamma-globulins with the concentration in each fraction being determined by densitometry. Although nephelometry and turbidometry are more accurate for measuring normal proteins, densitometry is considered the most accurate method for measuring the concentration of M-proteins, as will be discussed in the nephelometry/turbidometry section.

Improved separation has increased the discrimination of M-proteins so that monoclonal banding can be discriminated visually down to about 25–50 mg/dL (Roden et al., 2008). The resolution is dependent on the ionic strength of the buffer and the voltage, with higher voltage and more current causing better resolution.

Moreover, the buffer can be manipulated to cause higher resolution in different parts of the gel. Such resolution is called high resolution protein electrophoresis (HRPE) (Keren, 1994). If resolution is optimized over the whole gel, more bands are seen (Fig. 2) but often resolution is optimized in the gamma region where M-proteins most often migrate, producing more sensitivity for identifying tiny M-proteins. Although HRPE gives rise to 6–9 fractions, the standard densitometer profile remains 5 fractions with the beta-1-proteins and beta-2-proteins combined as shown in Fig. 3A.

Densitometry is the quantitative measurement of optical density through the gel by a spectrophotometer. The densitometer can be used to quantify the protein bands or densities as they are sometimes called. The densitometer can provide the percent of total density in each fraction from which the concentration of each fraction can be calculated from the total protein in the sample. Fig. 3A and B show the densitometer patterns of a normal and a gel containing an M-protein, respectively. Normally, the gamma globulin is diffuse as shown in Fig. 3A, but when a high concentration M-protein is present, the profile will appear as in Fig. 3B with a dense band on the gel and a spike on densitometry. Densitometry can distinguish M-proteins down to about 200 mg/dL while visual examination allows better discrimination down to about 25 mg/dL so that it is important to visually examine the gels.

Immunofixation electrophoresis (IFE)

The proteins are separated by electrophoresis but replicas are run in adjacent lanes. The lanes are treated with specific antibodies. The resultant antigen-antibody complex(es) becomes insoluble and precipitates in the gel as an immune complex. The rate of precipitation depends on the proportions of the reactants, temperature, salt concentration and the pH of the solution. The unreacted

Fig. 2 High resolution electrophoresis. In this case resolution is maximized over the entire gel and nine fractions are seen. Often resolution is maximized in the gamma regions and pre-albumin is not seen.

Fig. 3 Normal and M-spike densitometer and gel profiles. (A) Normal profiles. Notice the gamma region shows diffuse staining, indicating polyclonal Ig. (B) M-spike profiles. A large monoclonal restricted band is seen that appears as a spike on densitometry. This is a classical myeloma pattern. Notice the areas adjacent to the dark band are unstained, the diffuse staining seen in Fig. 3A is absent, indicating a decrease in normal Ig.

proteins are removed from the gel by washing and the antigen-antibody complex is best visualized by staining. Agarose is chosen because it is sufficiently porous to allow antibodies to enter the gel but sufficiently dense to trap precipitated immune complexes within the gel. According to the Heidelberg principle, if the antibody concentration is held constant, the amount of precipitate will increase as the antigen concentration increases until a zone of equivalency is reached. This is where maximum precipitation will occur. As the antigen concentration decreases below equivalency there will be less precipitate (antigen and antibody will become increasingly soluble). This phenomenon is called *prezoning*. Also, as the antigen increases above equivalency solubility will again incrementally increase (*prozoning*). *Prozoning* may be a problem with IFE because if the protein of interest (antigen) is at a very high concentration, it may react poorly with the antibody. In such cases, it may be necessary to dilute the sample containing the antigen to bring it back into the zone of equivalency. Generally, *prozoning* is not a problem with serum IFE because the concentration of M-protein is still within a range of equivalency and although there may appear to be a hole in the band as shown in Fig. 4, interpretation is not hindered.

The first method, used in clinical laboratories for diagnosis was immunoelectrophoresis (IEP) that was described by Grabar and Williams (1953). In IEP electrophoretic separation of replicate samples in agarose gels is conducted in multiple lanes in the first step. In the second step, immunoglobulin specific antiserum is placed in preformed troughs cut parallel to each lane. The gels are allowed to incubate in a closed chamber for 24–48 h, while the antisera and antigen diffuses into the gel. The proteins from the patient's serum which were separated by electrophoresis in the prior step migrate by diffusion towards the antisera. A precipitate develops, fixing the immunoglobulins in the form of an arc. Considerable skill is need to interpret the results, which are difficult to relate to routine protein electrophoresis (Levinson, 2009). A shorter narrow arc more distant from the trough and close to the antigen source indicates a decrease in antigen concentration, while a longer, thicker band close to the trough indicates an increased antigen concentration. However, if too high a concentration of protein is present, the precipitate may form very close to the trough or within the trough. The presence of an abnormal immunoglobulin is inferred from the comparing the size, shape, and distortions of the arc with the control. Identification of small abnormal components is particularly difficult.

IFE for M-proteins was described in 1973 by Ritchie and Smith (1976a,b,c) and Cawley et al. (1976) independently, for use in medical laboratories to identify monoclonal immunoglobulins in serum and urine. The major change in currently used methods is the availability of the complete procedure as a kit. As illustrated in Fig. 5, for serum, replicate electrophoresis of samples is performed in multiple lanes. Following this, the fractionated proteins on the electrophoretic strips are precipitated (fixed) into the agarose by overlaying with antisera specific for each type of immunoglobulin to be identified. After a wash step to remove unfixed proteins, (i.e., albumin, alpha and beta globulins) the strips are stained with a protein stain and washed to remove the excess stain. The separated immunoglobulins precipitate in a pattern that is easily related to the pattern on routine agarose SPE without fixation. The procedure can be performed in about 2 h. Moreover, there is greater sensitivity than on routine SPE or UPE without fixation because the mass of the antibodies binding to the specific protein increases the amount of protein that is stained to provide 3–5 × more sensitivity (Levinson et al., 2002). Nevertheless, since the procedure requires at least five lanes (i.e., minimum fixation one lane for each: SPE, IgG, IgA, IgM, kappa and Lambda), and very rarely IgD or IgE, a good deal of time and effort is required for each sample.

Fig. 4 Serum prezoning due to antigen excess.

Fig. 5 Illustration of IFE. After electrophoresis, each lane is overlaid separately with antibody specific for the common immunoglobulins: IgG, IgA, IgM, and kappa and lambda light chains—one type antibody/lane, causing each type of Ig to be fixed in the lane. In this case, IFE shows bands staining for IgA and lambda comigrating with the beta-1-globulins. Notice, the beta-1-band on SPE may look denser (darker) than normal (Fig. 3A) but not a lot darker. This increase in band density would be difficult to identify by SPE but the IgA-lambda M-protein is clearly identified as a band by IFE.

Migration of immunoglobulins on electrophoresis

IgG is a monomer and the most positively charged immunoglobulin and generally migrates in the gamma region towards the negative electrode. But immunoglobulins have a wide range of charges depending on their antigenic activity so that occasionally an IgG M-protein will migrate in the beta-region. IgM is a pentamer and because of its large size migrates in the gamma region although occasionally in plasma cell dyscrasia, it is aberrantly produced as an IgM monomer and may migrate faster towards the positive electrode. Also, in some cases two IgM bands are seen—a monomer and pentamer. IgA is the most negatively charged Ig and generally migrates in the beta-region. Occasionally, aberrant cells may synthesize a secretory dimer which is normally found in the digestive tract. In some case, two bands may be seen—a monomer and dimer. Fig. 6 shows an IFE profile defining where each polyclonal class of Ig normally migrate. Nevertheless, the variable region can have a wide variety of charges so, with the exception of pentameric IgM, immunoglobulins can theoretically migrate the entire length of the gel. Thus, occasionally IgG M-proteins are found in the beta region and even the alpha region. As a result, rarely intact M-proteins are identified in all gel areas. Fig. 7A shows IgG and IgA

Fig. 6 Migration of normal Ig. Ig from a normal individual was fixed on each lane. IgA is on the average the most negatively charged Ig and usually migrates in the beta region. IgG and IgM migrate in the gamma region with IgG somewhat more cathodally because on the average it has the most positive charge. Nevertheless, rarely a more negative charged IgG M-protein will migrate in the beta-region. Normal pentameric IgM almost always migrates near the origin near where the sample is applied (o). Occasionally, IgM monomeric M-proteins migrate faster even into the beta-region.

Fig. 7 Migration of M-proteins in the beta-region. There are many more IgG M-proteins than IgA. As such, occasionally IgG, like IgA will migrate into the beta region. (A) IgG and IgM M-proteins migrating in the beta-region. (B) Difficulty in discriminating beta migrating M-proteins. When M-proteins migrate in the beta-region, the beta-protein bands tend to mask the M-protein. If the M-protein is very low concentration, as shown, they may be masked by comigrating normal beta-proteins on SPE and only be picked up by IFE, as shown.

M-proteins migrating in the beta-region. Notice, these M-proteins are migrating with a mobility similar to normal beta proteins and low concentration IgG and IgA with such mobility may not be apparent on SPE because the beta band may appear normal (Fig. 7B). Also, when comigrating with the beta-band, it is not possible to estimate the exact concentration of the M-protein by densitometry. Only a rough estimate can be given by visual extrapolation from the densitometer value. One approach is to subtract the average value of the normal beta fraction from the measured densitometry concentration.

Interpretation of conditions other than monoclonal gammopathy by SPE

Although the main purpose of SPE in the clinical laboratory is to identify M-proteins, in some cases, SPE may be helpful in identifying or confirming some other conditions. These include: (1) Alpha-1-trypsin deficiency when the alpha-1- band is decreased. In this case quantitative measurement and genotyping for Pi types should be recommended. It is important to realize that except for ZZ most other Pi variants may not appear decreased because alpha-1-trypsin is a positive acute inflammatory protein and is often increased sufficiently to appear normal in disease. For this reason, genetic typing, not SPE, is recommended when alpha-1-trypsin deficiency is suspected. (2) Acute inflammation when there is an increased intensity of alpha-1 and alpha-2 and a polyclonal increase in gamma, and chronic inflammation when the albumin is decreased and there is a polyclonal increase in gamma. This latter profile may help confirm chronic infection or autoimmune disease. In autoimmune hepatitis a polyclonal elevation in gamma (often 2–3 ×) is considered an important diagnostic criterion (Friedman et al., 2010). (3) Nephrotic syndrome when the albumin band is substantially decreased due to hypoalbuminemia (often near or below 2 g/dL). In addition, the alpha-2 band may be more distinct and resemble a monoclonal band and the beta may be increased due to a relative increase in beta-lipoprotein. (4) Liver cirrhosis when the albumin band is significant decrease (again often near or below 2 g/dL) with a decrease in the alpha and beta proteins due to failure of liver synthesis and a substantial increase in gamma due to failure of liver Ig protein clearance (Ig breakdown) (Fig. 8). Additionally, beta-gamma bridging is always seen in liver failure. In beta-gamma bridging there is denser staining from the beta-2-proteins through to gamma. Beta-gamma bridging occurs because of a relative increase in IgA that mainly migrates in the beta region (Vavricka et al., 2009). In this case, the densitometer tracing may indicate an increase in the beta region but visual inspection will show that and there is an increase in baseline due to underlying immunoglobulin and that the alpha and beta bands are actually decreased (Fig. 8). (5) IgA nephropathy is often associated with increased serum polyclonal IgA. Thus, if renal disease in a patient is apparent, it is worth commenting on an elevation in polyclonal IgA as a part of an interpretive report.

Urine protein electrophoresis and IFE

Urine protein electrophoresis (UPE or UPEP)

UPE is performed identically to SPE, except it is recommended that the urine should be mechanically concentrated about 100 × prior to analysis (Keren et al., 1999). The reason for concentration is because it is important to identify monoclonal FLC in urine (monoclonal FLC in urine are called Bence Jones proteins in Honor of Henry Bence Jones who first discovered them and who is considered by many as the father of chemical pathology) (Rathore et al., 2012). It is important to recognize that although there may be a substantial amount of protein in urine due to structural kidney damage, the amount of monoclonal FLC may be at a low concentration. Thus, the amount of total protein in the urine is usually unrelated to the amount of BJP. And, although some systems claim to be more sensitive (Rodén et al., 2008), the recommend 100 × concentration seems wise.

UPE is important for identifying the anatomical defect(s) that lead to proteinuria (Peterson and Berggard, 1971; Laurell, 1972; Killingsworth, 1982). Normally proteins below about 40,000 molecular weight freely pass the glomerulus. Those above 40,000 passes less readily decreasing with molecular weight and negative charge. Serum albumin is by far the most abundant plasma protein but its molecular weight is about 67,000 and it is strongly negatively charged. As a result, normally, little albumin is found in the urine. There are about equal amounts of covalent and non-covalent kappa chain dimers in normal serum, while the lambda-chain dimers are largely covalent (Sølling, 1981). As a result, there is less filtration of lambda-chains causing a lower urinary kappa/lambda ratio than the 2/1 found in serum (Levinson and Keren, 1994).

The polyclonal FLCs tend to be positively charged and because of the low molecular weight readily pass the glomerulus. Normally, about 4–5 g/day of protein pass through the glomerulus with all except about 150 mg of protein being reabsorbed by the renal tubules. As illustrated in Fig. 9, normally, the resulting excretion is mainly polyclonal Ig FLCs, causing a dense gamma, some lower molecular weight alpha and beta globulins and a small amount of albumin.

Fig. 8 Cirrhotic pattern with beta-gamma bridging. Notice the densitometer tracing appears elevated for all fractions but this is because all Ig fractions are increased while actually the normal beta and alpha globulins are decreased due to liver failure causing reduced synthesis. IgA turns over faster than IgG and IgM but clearance is reduced in liver failure. As a result, it is relatively increased more than the others, giving rise to beta-gamma-bridging, since IgA tends to migrate in the beta-gamma region.

Fig. 9 Proteinuria patterns in disease. Notice, the normal is similar to the tubular since normally only a small amount of albumin is filtered into the urine and a relatively larger amount of gamma-globulin polyclonal FLC is secreted. Thus, the tubular pattern is meaningful only when there is an increase in total urine protein above normal reference limits.

In glomerular disease larger proteins pass more freely than normally through the leaky glomerulus so that large amounts of protein may pass, in some cases more than 3 g are excreted per day in the urine. Much of this protein is albumin (the most abundant protein in plasma). If the tubules are not diseased and still reabsorbing protein small globulins are still reabsorbed and a glomerular pattern is observed (Fig. 9). If the tubules are damaged but the glomerulus remains intact, normal amounts of protein pass the glomerulus but the small globulins cannot be reabsorbed, and more are excreted in the urine. These are largely polyclonal free light chains and alpha-2-microglobulins. This is called a tubular pattern. A tubular pattern is shown in Fig. 9. The tubular pattern is not much different from a normal pattern but the amount of protein excreted is increased. In severe tubular disease as much as 4 g/day of protein can be secreted so on the basis of total urine protein alone, it may appear to be glomerular disease. When both the glomerulus and tubules are damaged a mixed pattern is seen (Fig. 9). Combined glomerular and tubular damage usually give rise to protein excretion >5 g/day.

A high concentration of monoclonal FLC in serum that is filtered by the glomerulus such that the FLC concentration exceeds the tubular capacity for reabsorption, causes monoclonal free light chain to be excreted in the urine and overflow Bence Jones proteinuria occurs. This pattern is shown in Fig. 9. Since monoclonal FLC is toxic to the renal tubules so that the tubules can no longer reabsorb at a normal rate, overflow proteinuria occurs in most cases of monoclonal FLC disease.

Although UPE has value for identifying the anatomical injury, it has poor sensitivity for identifying BJP since the BJP may be masked/hidden by other protein bands in the urine and because immunological identification is required to certify the diagnosis of Bence Jones proteinuria or to help rule it out. For these reasons, UPE is always followed by urine IFE.

Most laboratories measure protein using protein binding dyes. The degree to which these dyes measure albumin and globulin varies and is peculiar to the dye. The degree to which these methods measure FLC is unclear. Very few laboratories use the biuret method which reacts with the peptide bonds in proteins, therefore, measuring all proteins more equally. As a result, except for biuret, these methods give only a rough estimation regarding quantitation of protein. Since the amount of protein estimated in urine is inaccurate in most cases and since the amount of Bence Jones protein in urine is estimated by densitometry from the amount protein in urine, in most cases, the amount of Bence Jones protein is inaccurate. Although some guidelines specify that certain amounts of Bence Jones protein in urine is indicative of extent of disease, it should be understood, that the concentration of BJP obtained from densitometry is usually a rough estimate (Levinson, 2000).

Urine IFE

Edelman and Gally (1962) showed that FLC of immunoglobulins were identical to the protein discovered by Dr. Henry Bence Jones in the urine of a patient with multiple myeloma in Bence Jones (1847) and Rathore et al. (2012). This observation linked the production of monoclonal FLCs to multiple myeloma. Dr. Bence Jones heated the acidified urine at 45–58 °C that produced a precipitate which disappeared upon further heating at 100 °C. The test is still valid but is poorly sensitive and was used to identify monoclonal FLCs in urine until the 1970s when IFE replaced it. Usually, monoclonal FLC in serum are at very low concentration and often comigrate with the beta-proteins so that they are not easily identified by SPE. Sometimes, they are more concentrated in urine which accounts for the visible precipitation by the heat test. But, more often, they are in low concentration in urine which explains why the heat test is poorly sensitive. But, unlike serum, urine can be mechanically concentrated by filtration so that the FLC concentration can be substantially increased prior to electrophoresis.

Urine IFE is performed similar to serum, except the urine is concentrated about 100×, regardless of the amount of protein, using a mechanical concentrator with a filter membrane that retains molecules greater than 20 kD. Twenty hour urine collection is recommended and if a Bence Jones protein is suspected three 24-h urines are recommended for rule out (Keren et al., 1999).

In some cases, viscous urine cannot be concentrated $100\times$, so it is concentrated as much as possible. When concentrating, it is desirable not to let the sample concentrate to dryness since proteins adsorbed on the walls may not be resolubilized. As such, the procedure is time consuming and somewhat tedious. Centrifugal concentrators concentrate more rapidly and reach an equilibrium so the solution cannot dry out but they are not desirable because they concentrate only about $5\text{--}10\times$.

The $100\times$ concentration is designed to provide the sensitivity to pick up very low concentration monoclonal FLCs. Theoretically, since UPE shows sensitivity to about 250 mg/L (25 mg/dL) and IFE is $3\text{--}5\times$ more sensitive, $100\times$ mechanical concentration brings the sensitivity of urine IFE to less than 1 mg/L. This provides great sensitivity for identifying very low concentration BJP, but when there are high concentration BJP, there may be extreme prozoning that can be misinterpreted by inexperienced examiners as no reaction.

Prozoning may be a problem with urine IFE because if the protein of interest (antigen) is at a very high concentration, it may react poorly with the antibody. Thus, urine IFE lacks a simple mechanism whereby dilution and titration produces antibody and antigen equivalency. An example of urine IFE used to identify a kappa-FLC is shown in Fig. 10. In some cases, the concentrated sample must be diluted and rerun causing more tedium. Moreover, since IFE may require eight lanes kappa, lambda, IgG, IgM, IgA and sometimes free kappa and free lambda, the procedure is expensive as well. In Fig. 10, at some high concentrations of kappa-FLC there is no reaction with the assay antibody because of prozoning or preozoning, also, antibody against FLC only has less avidity than that against free and bound light chain, so prozoning with FLC only antibody is always greater than with free and bound antibody.

In 1991, Harrison reported a pseudo-oligoclonal pattern, more commonly called ladder pattern (Harrison, 1991) that may appear in some urine specimens. Generally, the middle bands appear darker. This pattern (Levinson and Keren, 1994) may be a result of homologies in amino acid sequence, in the framework structure of the variable region that gives four chemically defined subgroups of kappa chains and five of the six lambda chains that have been serologically confirmed (Solomon and Weiss, 1987). These represent polyclonal not oligoclonal synthesis. This pattern is shown in Fig. 11. When interpreting urine IFE, it is important not to mistake this pattern for a Bence Jones protein. Moreover, in rare instances, it is possible that this pattern may cause difficulty in interpreting a tiny monoclonal FLC band (Hess et al., 1993).

Capillary electrophoresis

Some large laboratories use capillary zone electrophoresis (CE or CZE) to analyze serum proteins and identify M-proteins (McCudden et al., 2008). The proteins are separated in narrow bore glass capillaries based on charge and partitioning via non-covalent interactions to the wall surface. The proteins are measured by a spectrophotometer at an appropriate absorbance. The electropherogram is displayed in the typical five fractions as with agarose electrophoresis—albumin, alpha-1-globulin, alpha-2-globulin, beta-globulin and gamma-globulin. The sensitivity for identifying M-proteins is similar to that of HRPE, although oligoclonal bands may not be as easily identified (Bossuyt et al., 1998a,b). CE can be completely automated so that many samples can be run rapidly avoiding many of the preparations and steps needed with HRPE, resulting in quicker turnaround of patient results.

Fig. 10 Urine IFE demonstrating prozoning with dilution. A very high concentration kappa BJP is seen. $100\times$ concentration shows severe prozoning with the free and bound (F & B) appearing washed out in the center. The wash out is much less at $10\times$ concentrate and a clear, distinct band is seen when the urine was diluted $10\times$. The free kappa (F) only track show nothing at the $100\times$ concentrate because antibody against free kappa has less avidity than that against F & B causing severe prozoning - there is no apparent reaction. But at a $10\times$ dilution, Fkappa shows prozoning and at zero dilution a clear, distinct band is seen. When such a high concentration BJP is present, the normal $100\times$ concentrate may have to be diluted and IFE repeated to be certain of the interpretation.

Fig. 11 Ladder Pattern. Although diffuse, thorough examination shows three bands (arrows), usually, the middle band is darker.

CE can also be used for immunologically identifying classes of M-proteins and the nature of the light chain by immunosubtraction (Bossuyt et al., 1998a). For immunosubtraction, the sample is treated with antibody against each class and light chain to remove the M-protein by precipitation and after extraction, the sample is again analyzed. A computer program subtracts the missing area from the analysis prior to treatment to identify and quantify the M-protein. This approach is generally considered to be less sensitive than serum IFE, so most laboratories follow-up CE with IFE to identify M-proteins.

Nephelometry and turbidimetry to measure Ig in serum

Nephelometry and turbidimetry are used for quantifying serum proteins. When the antibody against a protein reacts with the protein, a precipitate forms which at equivalency is proportional to the concentration of the antibody. *Nephelometry* measures light energy scattered or reflected from the precipitate towards a detector that is not in the direct path of the transmitted light while *turbidimetry* measures the change in light when the detector is directly opposite the beam source. Theoretically, nephelometry is more accurate since with a detector at 90 degrees from the light beam there is no scatter until the precipitate appears so the detector should measure zero at baseline and increase to levels much higher than zero as the precipitate forms, while with turbidimetry there is maximum light prior to precipitation so as the precipitate forms the light detected decreases only a small amount from maximum. In actual fact, for measurement of most routine serum proteins the techniques are comparable in accuracy. This is because modern spectrophotometer can accurately measure tiny absorbance changes from maximum as the light decreases and because nephelometers are usually at 30 degrees from the light beam because at a 90 degree angle there is not enough light scatter to measure small increases. The light reaching the detector is compared to the amount from known protein mixtures. The amount of the unknown is determined from a standard curve calibrator. The antigen-antibody precipitate can be enhanced by reaction in polyethylene glycol 6000. Nevertheless, although these methods are sufficient for measuring the major serum proteins they are not sufficiently sensitive to measure proteins below about 10 mg/L (Whicher and Blow, 1980).

These methods are useful for measuring normal Ig but often inaccurate when M-proteins are measured because the antibodies and calibrators used with the assay are developed using the diverse normal immunoglobulins, whereas M-proteins often exhibit limited or incomplete antigenic determinants and may react incompletely with the antiserum and behave peculiarly compared with the calibrator. Thus, the concentration of M-proteins is often under or overestimated. Intact M-proteins are erroneously estimated about 10–20% of the time and FLCs most of the time since they are often peculiar as compared to the intact Ig calibrators and normal Ig (Levinson, 1992). Quantification of the normal immunoglobulin classes not involved in the disease may be useful for determining the functional degree of hypogammaglobulinemia. Because of these peculiar immunological properties, the best way to assess the concentration of a M-protein remains densitometry from SPE or UIPE.

Serum free light chain assays

Usually, monoclonal FLC in serum are at very low concentration that may not be detected by serum SPE or IFE but require urine IFE of a concentrated specimen to detect. Enhanced nephelometry uses antibodies attached to latex particles. This increases the

sensitivity of nephelometry well below the detection limit of 10 mg/L for standard nephelometry. The most widely used current method for assaying monoclonal free light chains in serum (sFLC assay) was developed by Bradwell et al. (2001, 2003). This method is presently available by automated analysis from, The Binding Site Group Ltd. (Birmingham, United Kingdom) as the Freelite assay. This assay uses an enhanced nephelometric assay. Polyclonal antibodies are directed against the hidden portion of kappa and lambda light chains that allows measurement down to concentrations of about 1 mg/L, comparable to urine IFE on concentrated urine specimens. The assay uses polyclonal FLC for calibration in an attempt to reduce some of the peculiar reaction between antibody and monoclonal FLC as compared to standard nephelometry that uses intact Ig as the calibrator. Nevertheless, peculiar reaction with antibodies and interference by polyclonal FLC remains a problem (Levinson, 2016).

Although there are now other assays that may provide similar information the N Latex FLC nephelometric from Siemens Healthineers, Eschborn, Germany and the Sebia FLC, based on solid-phase sandwich enzyme-linked immunosorbent assay (ELISA), Sebia, Evry, France (Schiederdecker et al., 2020), most clinical information has been obtained using the Freelite assay and recommendations of the IMWG are largely based on this assay. Therefore, only the reference ranges and recommendations regarding the Freelite assay will be discussed here. Serum normal 95% reference ranges for FLC kappa and lambda concentrations by Freelite assay have been defined as 3.3–19.4 mg/L for kappa FLC, 5.7–26.3 mg/L for lambda FLC and 0.26–1.65 for the kappa/lambda ratio (Katzmann et al., 2006; Dispenzieri et al., 2009). Up-to-date clinical use for this assay is described by the IMWG at <https://www.myeloma.org/resource-library/international-myeloma-working-group-imwg-guidelines-serum-free-light-chain> Accessed 1/27/2021 but the definitive document remains in journal form (Dispenzieri et al., 2009).

Early data indicated that although polyclonal FLC may be elevated in some diseases causing an increase in FLC kappa and lambda concentrations, an abnormal kappa/lambda ratio indicated myeloma (Katzmann et al., 2002) but later studies showed that kidney dysfunction may require reference ranges as high as 251 mg/L for both serum kappa-FLC and lambda-FLC and can alter the ratio as well (Hutchison et al., 2008a,b). Since many patients with myeloma exhibit renal dysfunction, results of serum FLC analysis is best assessed in the context of other clinical and laboratory indicators.

The assay has many advantages over monitoring BJP by urine IFE and requires only a single serum measurement as compared to collecting and measuring 24 h concentrated-urine collections to identify most cases of monoclonal FLC. Serum can be directly assayed. Although the assay requires many dilutions due to non-equivalent reactions between antibody and antigen, which caused a good deal of tedium in the earliest manual versions, the automated versions provide a rapid, direct way to measure monoclonal FLC in serum. This provides a simpler way to monitor monoclonal FLC changes for changes in disease status. Moreover, there is evidence that high baseline values may have prognostic indications for M-protein gammopathies, especially smoldering (asymptomatic) myeloma, where serum FLC kappa/lambda ratios of <0.125 or >8 or >100 mg/L suggests early treatment may be appropriate (Larsen et al., 2013; Garcia de Veas Silva et al., 2016).

The development of this sFLC assay added a new dimension to the diagnosis and monitoring of plasma cell dyscrasia. In fact, some suggested that urine IFE is no longer needed for diagnosis of FLC diseases and can be replaced by sFLC assays (Katzmann et al., 2006, 2009; Holding et al., 2011). Nevertheless, there are two basic weaknesses that limit its usefulness and is the reason that urine IFE remains important for diagnosis and monitoring of monoclonal FLC.

1. The assay is not quantitative in a proportional way between different patients. This is because monoclonal FLC react differently with assay antibodies than the polyclonal FLC calibrator so that, although it is possible to follow trends within any one patient, it is not possible to quantitate the amount of monoclonal FLC in an absolute sense. Besides, this peculiarity of the monoclonal FLC causes severe over estimation of monoclonal FLC in some cases as compared to densitometry (de Kat Angelino et al., 2010; Levinson, 2011a,b) and substantial underestimation in other cases (Tate et al., 2007, 2009).
2. Since the assay measures polyclonal FLC, the assay is very good for detecting monoclonal FLC during disease progression, when the monoclonal clone has suppressed polyclonal production. But as the disease regresses with treatment the normal clones increase and polyclonal production resumes while monoclonal FLC is suppressed, so that the polyclonal FLC interferes with measurement of the monoclonal FLC at lower monoclonal FLC concentrations. (Levinson, 2011a,b). For this reason, the IMWG recommends that that about 100 mg/L of serum FLC, the assay can no longer reliably distinguish whether or not the monoclonal free light chain is present and urine IFE is recommended when accessing response to therapy (Dispenzieri et al., 2009).

The IMWG (Dispenzieri et al., 2009) recommends that serum FLC replace urine IFE for initial screening for plasma cell dyscrasias and related diseases except amyloidosis AL where urine IFE and serum FLC is still recommended for initial screening. This is because FLC concentrations are often very low in amyloidosis AL and it has been shown that urine IFE is slightly more sensitive while the two assays together pick up more true positives than either alone (Palladini et al., 2009). Moreover, the IMWG recommends serum FLC assay be used only for monitoring free light chain-multiple myeloma, amyloidosis AL, oligosecretory disease and nonsecretory disease when applicable.

IgD and IgE

IgD myeloma is rare, occurring only in about 1–2% of myeloma cases while IgE myeloma has only been reported in about 50 cases (Pandey and Kyle, 2013). When a patient has only staining for light chain in serum but the immunofixation is negative for IgG, IgA, or IgM, the possibility of IgD or IgE monoclonal immunoglobulin must be considered. If there is also a Bence Jones protein in urine, one might conclude the serum band is a FLC, but a Bence Jones protein is associated with IgD myeloma about 70% of the time with

lambda predominating 2–1 over kappa (Djidjik et al., 2015). Therefore, a Bence Jones protein in urine or a positive serum FLC result does not rule out IgD myeloma. Moreover, the concentration of these M-proteins tends to be low and often more difficult to detect than IgG myeloma. IgD myeloma is usually associated with hypogammaglobulinemia (Djidjik et al., 2015), so a small M-protein in serum staining only for light chain and associated with hypogammaglobulinemia would be especially suspect.

The exact diagnosis of IgD myeloma is often delayed, but since treatment for these are the same as for other types of myeloma (Shihabi, 2006), identification of multiple myeloma seems the more important factor. Generally, patients with IgD myeloma do more poorly than those with other types, except light chain myeloma, but there is evidence that the FLC commonly found in this type of myeloma is the main reason for the poor prognosis (Djidjik et al., 2015). Therefore, delay in exact diagnosis may not hinder treatment.

Plasma cell dyscrasias, recommend testing and symptoms

Introduction

The prototype for active multiple myeloma is characterized by a serum M-protein of greater than 3 g/dL with reduced polyclonal Ig, while benign gammopathy typically shows an IgG M-protein less than 2 g/dL (Kyle et al., 2006). Fig. 12 illustrates typical electrophoretic gammopathy profiles in various conditions (Kyle et al., 2007). Active myeloma implies there is end organ damage attributed to the disease (CRAB). In actual fact, some persons with active myeloma may secrete an M-protein of <3 g/dL—so called oligo-secretory (Fig. 14A), no M-protein at all (non-secretory), or a FLC without an intact M-protein (light chain—multiple myeloma), so present recommendations do not define the concentration of the M-protein in active myeloma, while an M-protein of <3 g/dL may be found in benign MGUS. Moreover, IgA M-proteins define a greater risk of developing myeloma (Kyle and Rajkumar, 2011). Also, some persons with so called smoldering (asymptomatic) myeloma exhibit an M-protein >3 g/dL but do not demonstrate end organ damage and may not need other than supportive treatment until organ damage begins to develop. Such a densitometer profile is also illustrated in Fig. 12.

Rarely, two monoclonal bands are identified (Srinivasan et al., 2016). Double banding may indicate a biclonal gammopathy—a mutation in two different clones. If one band is kappa and the other is lambda, it is clearly biclonal but if both bands are kappa or lambda, it is more likely due to asynchronous synthesis in one cell line of the clone or class switching if one band is IgG-kappa and the other IgA-kappa. The incidence of two bands is estimated to be 2–6% and clinically, there is no difference in clinical outcome between two band gammopathy and monoclonal gammopathy (Srinivasan et al., 2016). Two bands may also be observed when there is an intact Ig and a high concentration FLC in serum. Beside it is not uncommon to observe two monoclonal IgA or IgM bands migrating close to one another, where one is a monomer and one a dimer, or one is a monomer and the other a pentamer, respectively. Also, malignant cells can secrete a whole M-protein and a fragment of the protein. Some two band gammopathies are illustrated in Fig. 13A–C.

The present definitions of M-protein associated diseases differ from those of the past. Advances in laboratory and imaging techniques have improved so that the criteria for CRAB features are now well defined and importantly treatment options have greatly improved. Data shows early intervention in high-risk asymptomatic patients can extend survival (Mateos et al., 2013; Rajkumar et al., 2014).

IgM M-proteins rarely presents as myeloma but usually represents a non-Hodgkin syndrome that is readily treatable in most cases. Most IgM M-proteins are kappa and an IgM-lambda may be more reason for concern that myeloma may develop.

Fig. 12 Typical M-protein patterns.

Fig. 13 Multiple M-proteins (bands) gammopathy. Arrows indicate M-proteins. (A) Two band gammopathy due to class switching. The M-proteins are IgG-kappa and IgG-lambda, suggesting class switching from IgG to IgA occurred. (B) Two band gammopathy due to biclonal production. The M-proteins are kappa and lambda, indicating a biclonal gammopathy. Notice the IgG-kappa migrated very rapidly into the alpha-region of the gel. (C) Two band gammopathy due to intact Ig and FLC.

Thus, MGUS has been divided into IgM MGUS and non-IgM MGUS (Kyle et al., 2018). IgM typically arises from a CD20+ lymphoplasmacytic cell that has not undergone switch recombination, and this disease type is associated with a risk of progression to lymphoma or Waldenstrom's macroglobulinemia. In contrast, non-IgM MGUS typically arises from mature plasma cells that have undergone switch recombination, somatic mutation and antigen selection (Bakkus et al., 1992) and is associated with a risk of progression to multiple myeloma. Thus, of 207 patients with IgM MGUS 11 developed Waldenstrom's, 17 others non-Hodgkin's lymphoma, 3 chronic lymphocytic leukemia and zero developed myeloma. Nevertheless, both IgM and non-IgM MGUS can progress to amyloidosis AL (Kyle et al., 2018).

Plasmacytoma is a tumor of plasma cells. The plasma cells in plasmacytoma are identical to those seen in multiple myeloma, but they are not dispersed throughout bone or in blood, instead they form discrete masses of cells. Plasmacytomas usually show lower concentrations of M-proteins than in myeloma with more than 50% of patients with solitary plasmacytoma showing M-proteins of

Fig. 14 M-protein associated Plasmacytoma. Notice, that the M-protein is of low concentration but there are three bands (arrows). The pattern appears oligoclonal but all bands are lambda and a plasmacytoma was identified, suggesting the bands were monoclonal. Eventually, this patient developed multiple myeloma. Compare this profile with multiple banding in Fig. 13.

≤ 0.5 g/dL (Dingli et al., 2006). Fig. 14 shows an M-protein pattern from a patient with plasmacytoma. Although some patients with plasmacytoma are cured (Mignot et al., 2020), others progress to multiple myeloma.

Solitary plasmacytoma is a tumor composed of plasma cells that is restricted to a single area of the body. Usually, these tumors are in a bone but sometimes in an organ. Solitary plasmacytoma of the bone can sometimes be cured with radiation therapy, surgery and chemotherapy. However, many people with solitary plasmacytoma eventually develop multiple myeloma (Dingli et al., 2006). Extramedullary plasmacytoma is a tumor that develops in the lungs, sinuses, nasopharynx, or other organs. More than half of people with extramedullary plasmacytoma are cured with radiation therapy (Chao et al., 2005).

FLC multiple myeloma (LCMM) (Rafae et al., 2018) is found in as much as 15% of cases. Plasma cells show rearrangements in immunoglobulin heavy chains at the DNA level resulting in an inability to produce heavy chain (Magrangeas et al., 2004). LCMM appears to have a poorer prognosis as compared to IgG or IgA myeloma. Much of the morbidity and mortality may be associated with renal disease since high monoclonal FLC concentrations in the proximal tubule of the kidney overwhelm the reabsorption capacity resulting in the formation of casts in the distal tubules, causing cast nephropathy (Rafae et al., 2018) and occasionally FLC deposition and crystallization occurs within proximal tubules. Amyloidosis AL that may damage the kidney occurs in about 5–10% of cases.

Fig. 15 illustrates electrophoretic profiles from a patient with LCMM. As in most advanced myeloma cases, polyclonal Ig in serum is reduced. The serum free light chain assay usually shows an abnormal kappa/lambda ratio and urine IFE invariably shows a Bence Jones protein. Often, as shown in Fig. 15, the serum monoclonal FLC is not high enough to observe a band on SPE or the monoclonal FLC is comigrating with the beta proteins so that only hypogammaglobulinemia is seen. In many cases, serum IFE will show a small band. Thus, it is worthwhile to perform serum IFE on all samples showing significant hypogammaglobulinemia. Although there are recommendations by professional societies regarding prognostic and diagnostic indications for cutoff value concentrations of monoclonal FLC in serum and urine, it should be remembered that neither of these methods are constantly quantitative accurate or reliable (Levinson, 2000, 2016).

Fig. 15 FLC myeloma. In this case, SPE shows no M-protein but hypogammaglobulinemia. Urine IFE indicates a kappa-M protein (kappa-BJP) (arrows). Hypogammaglobulinemia on SPE with a BJP in urine is a classical picture for FLC myeloma.

Criteria for Diagnosis of Multiple Myeloma and Benign Monoclonal Gammopathy Assessed 1/29/2021: <https://www.myeloma.org/international-myeloma-working-group-imwg-criteria-diagnosis-multiple-myeloma>. For more detail (Rajkumar et al., 2014)

Definition of active multiple myeloma

Clonal bone marrow plasma cells >10% or biopsy-proven bony or extramedullary plasmacytoma and any one or more of the following CRAB features and myeloma-defining events:

- Evidence of end organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:
 - Hypercalcemia: serum calcium >11 mg/dL. Hypercalcemia on initial presentation is not common but suggests advanced disease.
 - Renal insufficiency: creatinine clearance <40 mL per minute or serum creatinine >2 mg/dL.
 - Anemia: hemoglobin value of >20 g/L below the lowest limit of normal, or a hemoglobin value <100 g/L
 - Bone lesions: one or more osteolytic lesion on radiological examination.
 - Any one or more of the following biomarkers of myeloma defining events. 60% or greater clonal plasma cells on bone marrow examination. Historically 30% is sufficient
 - Serum involved/uninvolved free light chain ratio of 100 or greater, provided the absolute level of the involved light chain is at least 100 mg/L. The uninvolved free light chain is typically in, or below, the normal range.
 - More than one focal lesion on MRI that is at least 5 mm or greater in size.

Definition of smoldering myeloma

In the past, asymptomatic myeloma was divided into smoldering and indolent. Smoldering was defined as a serum M protein >3 g/dL and/or bone marrow clonal plasma cells $\geq$ 10%, or urinary monoclonal protein estimated to be $\geq$ 500 mg per 24 h and absence of anemia, renal failure, hypercalcemia, and lytic bone lesions (CRAB symptoms) while Indolent multiple myeloma was the same as smoldering except for mild anemia or few small lytic bone lesions and absence of other symptoms. More recently, asymptomatic has largely been replaced by smoldering while the term indolent is no longer in use. The main reason being that therapies have improved so that treatments are initiated sooner, even with minimal symptoms.

Risk factors for progression to active myeloma over 5–15 years are as might be expected: include IgA >risk than IgG, bone marrow plasma cells <20% less risk than 20–50% less risk than >50%, M-protein concentration <4 g/dL less risk than >4 g/dL, more suppression of uninvolved Ig greater risk than less suppression, urinary FLC greater risk than no FLC (Kyle et al., 2007). More recently, very elevated serum FLC (Larsen et al., 2013; Garcia de Veas Silva et al., 2016). Disease management in smoldering myeloma often consists of monitoring every 3 months, treatment with bisphosphonates and supportive care.

Definition of MGUS

Non-IgM MGUS

Benign monoclonal gammopathy with low concentration M-protein in serum, usually IgG, occurs in about 4.6% of persons over 70 years old, about 1.7% of those 50–59 years old and about 6.6% of those over 80 (Kyle et al., 2006). There is a slight predominance in men over women. Fig. 16A illustrates typical electrophoretic profiles for M-proteins that are apt to be benign. Notice that, not only are the M-proteins tiny but the uninvolved Ig appears appropriate in concentration.

Progression to active myeloma depends mainly on the concentration of the M-protein and the age of the patient. Thus with concentrations <5 g/L, 6% progress; with 10 g/L, 7% progress; with 15 g/L, 11% progress, with 20 g/L, 20% progress, with 25 g/L, 24% progress, and with 30 g/L, 34% progress to active myeloma (Kyle et al., 2002). Older persons with very low concentration M-proteins are much more likely to die from something else before developing active myeloma. Generally, periodic monitoring of the concentration of the M-protein and whether or not symptoms have developed is sufficient. In some cases, very low concentration M-proteins will not be present on repeated testing (Strobel, 2003). Rarely oligoclonal banding may be mistaken for a low concentration M-protein.

Oligoclonal banding and FLC-MUGS

Oligoclonal banding usually stains for both kappa and lambda but may stain for kappa or lambda only. In the latter case, it may be very difficult to differentiate from a monoclonal and further work up may be appropriate. Oligoclonal banding may occur when there is a peculiar activation of the immune system (Levinson and Keren, 1989). Fig. 16B illustrates this pattern. Close examination of the IFE pattern shows that the bands in Fig. 16B are both kappa and lambda.

Also, there can be a MGUS associated with monoclonal FLC. This condition was rarely encountered in the past because low concentration monoclonal FLC was only identified in concentrated urine by IFE and urine electrophoresis was not performed on persons without renal disease. But, with the introduction of the simple to perform serum FLC assay, orders for monoclonal FLC are more common.

Fig. 16 Low concentration banding. (A) Typical MGUS. Notice polyclonal Ig appears normal. The M-proteins (arrows) are very low concentration: one is lambda and the other kappa. (B) Oligoclonal banding. In this case, the low concentration banding appears oligoclonal since there are two bands (arrows) and close examination shows the banding stains for kappa and lambda. Such oligoclonal banding often disappears eventually. Such banding is very similar to that seen with MGUS (Fig. 16A), especially if the oligoclonal banding is only kappa or lambda.

The IMWG defines non—IgM MGUS as:

- Serum monoclonal protein <30 g/L
- Clonal bone marrow plasma cells <10%
- Absence of CRAB symptoms or amyloidosis that can be attributed to the plasma cell proliferative disorder

and

Free Light Chain MGUS as:

- Abnormal FLC kappa/lambda ratio (<0.26 or >1.65)
- Increased level of the appropriate free light chain (increased kappa FLC in patients with ratio >1.65 mg/L and increased lambda FLC in patients with ratio <0.26 mg/L)
- No immunoglobulin heavy chain expression on immunofixation
- Absence CRAB symptoms or amyloidosis that can be attributed to the plasma cell proliferative disorder
- Clonal bone marrow plasma cells <10%
- Urinary monoclonal protein estimated <500 mg/24 h

The IMWG defines IgM MGUS as:

- Serum IgM monoclonal protein <30 g/L
- No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, hepatosplenomegaly, or other end-organ damage (CRAB) that can be attributed to the plasma cell proliferative disorder or amyloidosis.

The IMWG defines plasmacytoma as:

Solitary Plasmacytoma:

- Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells
- Normal bone marrow with no evidence of clonal plasma cells

- Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion)
- Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) or amyloidosis that can be attributed to the plasma cell proliferative disorder

Solitary plasmacytoma with minimal marrow involvement:

- Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells
- Clonal bone marrow plasma cells <10%
- Normal skeletal survey and MRI (or CT) of spine and pelvis (except for the primary solitary lesion)
- Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) or amyloidosis that can be attributed to the plasma cell proliferative disorder

POEMS syndrome and other neurological complications of M-proteins

An estimated 10% of polyneuropathies are associated with M-proteins (Ropper and Gorson, 1998; Dispenzieri and Kyle, 2005; Chaudhry et al., 2017). These include: multiple myeloma and Waldenstrom macroglobulinemia, amyloidosis AL, cryoglobulinemia, POEMS syndrome, MGUS or polyneuropathy associated with MGUS and chronic inflammatory demyelinating polyradiculoneuropathy, more commonly called chronic inflammatory demyelinating polyneuropathy (CIDP) where about 10% of patients exhibit an M-protein (MGUS) (Kelly Jr. et al., 1981). Also, some therapies for plasma cell disease such as thalidomide, and bortezomib can cause neurotoxicity and have become a leading cause of peripheral neuropathy in plasma cell dyscrasias (Mohty et al., 2010).

Whereas IgG is the most common class of paraprotein in patients with MGUS, IgM is more frequent in those with neuropathy (60%), followed by IgG (30%) and IgA (10%). These antibodies with apparent unknown significance, especially IgM, may have antibody activity against myelin associated protein and also cross react with other glycoproteins with similar structure in myelin (Ropper and Gorson, 1998; Chaudhry et al., 2017). Because of the frequent association of M-proteins with polyneuropathies, most neurologists request SPE on all such patients. Many of these monoclonal gammopathies are very low concentration tiny bands so that all SPE samples from persons with polyneuropathies should be examined visually and it is wise to perform IFE on such samples even if no visible band is observed.

POEMS is a paraneoplastic syndrome due to an underlying plasma cell neoplasm characterized by disease in diverse organs with multifarious symptoms. The major criteria that must always be present are polyneuropathy and an M-protein. Although there is always a clonal plasmacytosis, usually it tends to be mild, usually less than 10% plasma cells with a low concentration M-protein. Since M-proteins are commonly associated with polyneuropathies, POEMS syndrome diagnosis is often delayed. Many patients with POEMS syndrome have an initial diagnosis of CIDP. CIDP is similar to Guillain-Barre syndrome (GBS) but can be distinguished from GBS by its relapsing and progressive course (Jones et al., 2011). It is important to differentiate between CIDP and POEMS since CIDP is treated with immunosuppressive, intravenous immunoglobulin IVIG, or plasma exchange therapy (Ropper and Gorson, 1998; Dispenzieri, 2011). On the other hand, POEMS is clearly linked to plasma cell dyscrasia and most successful outcomes have been achieved by directing therapy towards the clonal plasma cell disorder. Autologous stem cell transplantation (ASCT) (Zhao et al., 2019) appears to be an effective treatment (D'Souza et al., 2012; Cook et al., 2017).

Other major criteria include, Castleman disease, vascular endothelial growth factor (VEGF) elevation and osteosclerotic bone lesions, rather than lytic. In fact, POEMS syndrome is synonymous with osteosclerotic myeloma (Kelly et al., 1983; Miralles et al., 1992). It should be noted that there is a Castleman disease variant that occurs without evidence of a clonal plasma cell disorder that should be considered separately (Dispenzieri, 2019). Besides minor criteria associated with POEMS syndrome include organomegaly, extravascular volume overload (edema, pleural effusion, or ascites), endocrinopathy, skin changes, papilledema and thrombocytosis/polycythemia.

VEGF is a potent multifunctional cytokine that was first identified as a tumor secreted protein. It both induces angiogenesis and is a potent vascular permeabilizing agent, with a potency 50,000 × that of histamine (Dvorak et al., 1995). VEGF is the most recent of the specific criteria. It rises to 1500 pg/mL or above in POEMS syndrome (Watanabe et al., 1996, 1998; Scarlato et al., 2005). Plasma VEGF was not elevated in myeloma (Soubrier et al., 1997; Briani et al., 2011). Nor was VEGF elevated in the serum of patients with other plasma or B-cell dyscrasias including: Waldenstrom macroglobulinemia, MGUS (Watanabe et al., 1996; Soubrier et al., 1997; Scarlato et al., 2005), amyloidosis (Briani et al., 2011), or patients with GBS, CIDP, or other neurological diseases where average values in studies were less than 500 pg/mL (Watanabe et al., 1996, 1998; Soubrier et al., 1997; Briani et al., 2011).

Systemic capillary leak syndrome (SCLS) is an extremely rare disease of plasma extravasation and vascular collapse resulting in hypotension and shock with less 126 cases reported (Amoura et al., 1997; Wall et al., 2011) Like POEMS, nearly all patients with this SCLS have been shown to have a low concentration M-gammopathy with less than 10% plasma cells in bone marrow and an elevated VEGF above 1500 pg/mL.

POEMS seems to affect men in about a two to one ratio as compared to women and although the average age appears to be about 50, POEMS has been diagnosed in those as young as 27 and as old as 80 (Nakanishi et al., 1984; Soubrier et al., 1994; Dispenzieri et al., 2003). In an investigation of 99 patients (Dispenzieri et al., 2003), most patients exhibited a low concentration M-protein with only 7 showing a M-protein of >20 g/L. 86% had less than 10% plasmacytosis, 97% of 99 patients exhibited osteosclerotic

lesions, 44 patients had an IgA M-protein, 40 an IgG M-protein and only 1 an IgM. All were lambda-gammopathies. These results were largely consistent with two other studies (Nakanishi et al., 1984; Soubrier et al., 1994).

It has been hypothesized that like SCLS many of the extravascular volume overload manifestations of POEMS including papilledema, peripheral edema, pleural effusion, ascites and polyneuropathy are caused by the VEGF and other permeabilizing cytokinins (Watanabe et al., 1998; Briani et al., 2011). VEGF increased microvascular permeability of the blood brain barrier in an animal model inducing endoneural edema (Dispenzieri, 2011) and there appears to be a correlation between VEGF serum levels and endoneural vessel damage in patients (Scarlato et al., 2005). Like VEGF, N-terminal propeptide of type I collagen may be a future novel marker for POEMS syndrome (Wang et al., 2014; Dispenzieri, 2019).

Lambda M-proteins have been considered characteristic for POEMS syndrome but kappa-M proteins have been well described (Dursun et al., 2005; Levinson, 2012a,b; Pulivarthi and Gurram, 2018). As a result, patients with kappa M-proteins may be considered to have CIPD or simply MGUS associated polyneuropathy.

These methodological and clinical issues highlight the difficulties in the investigation of POEMS. The M-protein is usually of low concentration and easily mistaken for MGUS. Moreover, bone marrow analysis often shows only a slightly elevated or a normal level of plasma cells and lytic lesions are often absent. The syndrome may be mistaken for polyneuropathy associated with MGUS (Sghirlanzoni et al., 2000) or CIDP. Although kappa-gammopathies have been found associated with POEMS syndrome when osteosclerotic lesions and λ -M-proteins are not present, clinicians may be reluctant to diagnosis POEMS. They may ascribe the condition to the more benign polyneuropathy associated with MGUS that is more often kappa than lambda (Ropper and Gorson, 1998; Dispenzieri and Kyle, 2005) or to MGUS associated with CIDP. These are reasons why it is some important to assess carefully all the criteria for diagnosis (Dispenzieri, 2019).

Also, M-proteins associated with POEMS syndrome are usually at low concentrations and more than 50% are IgA that may co-migrate with the beta-proteins. Such M-proteins may not be obvious and may be difficult to detect by SPE. As with other polyneuropathies, it is important that IFE be performed on all specimens if POEMS syndrome is suspected and a M-protein is not identified by SPE. Also, if no M-protein is identified by SPE and serum FLC and urine IFE should be ordered to rule out a FLC (Dispenzieri, 2019). Fig. 17 illustrates a low concentration IgA M-protein co-migrating with the beta-1-proteins that was identified in a patient with a diagnosis of POEMS syndrome.

The IMWG defines POEMS Syndrome as:

- Polyneuropathy mandatory major criteria is required for diagnosis.
- Monoclonal plasma cell proliferative disorder mandatory major criteria is required for diagnosis
- Any one of the three other major criteria is required:
 1. Sclerotic bone lesions
 2. Castleman's disease
 3. Elevated levels of VEGFA
- Any one of the following 6 minor criteria is required:
 1. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy)

Fig. 17 IgA-lambda M-protein in POEMS. Notice that the IgA-lambda M-protein (arrows) is co-migrating with the beta-2-globulin and although the SPE beta-2-band appears a bit more dense than normal, there appears to be appropriate amounts of polyclonal Ig, making this M-protein very difficult to detect by SPE. This M-protein is only truly apparent on IFE. Since about 50% of M-proteins in POEMS syndrome are IgA, IFE should always be performed when no M-protein is apparent and POEMS syndrome is suspected.

2. Extravascular volume overload (edema, pleural effusion, or ascites)
3. Endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, pancreatic)
4. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid, plethora, acrocyanosis, flushing, white nails)
5. Papilloedema
6. Thrombocytosis/polycythemia

Amyloidosis AL

Amyloidosis is a deposition of proteinaceous material in a tissue. When viewed by X-ray diffraction, these deposits form fibrils in an anti-parallel conformation and beta-pleated sheet structure (Vaxman and Gertz, 2019). The exact reason that some proteins form this structure is poorly understood. Infiltration of tissues by amyloid causes dysfunction. When amyloidosis is suspected a biopsy of tissue will exhibit apple-green birefringence in the polarizing microscope when stained with Congo red. The simplest tissue to biopsy is the abdominal fat pads. If amyloidosis is suspected and the fat pads are negative, it is best to biopsy the tissue involved (Vaxman and Gertz, 2019). Table 1 outlines the more common types of amyloidosis along with the abnormal protein and tissues involved (Lachmann et al., 2002; Hassan et al., 2005; Shah et al., 2006; Vaxman and Gertz, 2019).

The most common tissues that lead to diagnosis of amyloidosis AL are the kidney and heart. Although the central nervous system is usually not affected, peripheral nervous system complications are common, especially carpal tunnel syndrome. It is important to differentiate ATTR most commonly wild type (Senile, Table 1) from amyloidosis AL in the heart because Senile amyloidosis is slow progressing while AL is rapid (Shah et al., 2006). Moreover, the ATTR (Senile) and ATTR (familial/mutant) are treated differently than amyloid AL. Amyloidosis of the heart is a cause of heart failure and is often recognized by echocardiology as a mainly restrictive cardiomyopathy with conduction system disturbances. A granular sparkling refractile myocardium that along with septal wall thickening is pathognomonic for the disease. Recent guidelines have been published (Garcia-Pavia et al., 2021). Amyloidosis of the kidney is often suspected as a result of proteinuria.

Because amyloidosis AL is the most common type of amyloidosis, after positive biopsy for amyloid, the serum FLC assay should be performed (elevation in kappa or lambda and/or kappa/lambda ratio) and concentrated urine should be examined for Bence Jones proteinuria. If these are positive for monoclonal FLC, this is presumptive evidence for amyloidosis AL. If negative for FLC bone marrow can be examined for kappa/lambda dominance (Falk et al., 1997; Vaxman and Gertz, 2019). If still negative for FLC, immunochemistry for AA and genetic testing for the other types of amyloidosis can be conducted (Falk et al., 1997).

Amyloidosis AL is more often lambda than kappa with a 2/1 ratio and there is some evidence that lambda amyloidosis is more aggressive. The median age for amyloidosis AL is 60 years old. It is important to identify a monoclonal FLC because MGUS is fairly common in older people and it has been shown that 34 of 350 patients (9.7%) were misdiagnosed as AL because a MGUS was found, when they actually manifested other types of amyloidosis (Lachmann et al., 2002). Most of these misdiagnoses occurred because, although a MGUS was identified which led to the assumption of amyloidosis AL, monoclonal FLC was absent.

Amyloidosis AL is usually associated with myeloma or less often Waldenstrom's macroglobulinemia. When amyloidosis AL occurs in the absence of overt plasma cell or lymphocyte dyscrasia, it may be difficult to detect because bone marrow commonly shows <5% plasma cells and is amyloid positive only about 30% of the time. A monoclonal FLC is often not observed by SPE or serum IFE because the concentration in serum is too low and serum polyclonal immunoglobulins are often adequate (not depressed as in FLC myeloma). Fig. 18 illustrates SPE and urine IFE from patients with amyloidosis AL. Urine IFE has been shown to be somewhat more sensitive than serum FLC for identifying monoclonal FLCs in amyloidosis AL (Palladini et al., 2009), although

Table 1 Commonest types of amyloid.

Type	Abnormal protein	Tissues
AL (previously primary)	Monoclonal light chain Lambda/kappa 2/1	Heart Gastrointestinal track and Liver Kidney Peripheral neuropathy Soft tissues: Carpal tunnel syndrome, Macroglossia are common
AA (secondary)	Amyloid A protein (AA)	Kidney Gastrointestinal track and Liver
ATTR (familial/mutant TTR)	Transthyretin (TTR) (Prealbumin)	Peripheral neuropathy Heart Kidney
Senile systemic ATTR	Transthyretin (wild type)	Heart Diffuse organ involvement
Other familial types	Fibrinogen A α (most common) Apolipoprotein A-I Lysozyme	Peripheral neuropathy Heart Kidney

Fig. 18 Profiles in Amyloidosis. Notice a M-protein (BJP) is seen in urine but not M-protein is apparent by SPE. Moreover, even with $100\times$ concentration of the urine, the BJP may be at too low a concentration to be apparent on UPE but only show up on the more sensitive IFE. Compare these very low concentration profile with the very large concentration BJP from a patient with light chain myeloma seen in Fig. 10 where a very large concentration BJP caused prozoning until diluted.

both are recommended for initial screening as they complement one another. As with other plasma cell dyscrasias treatment is aimed towards clonal plasma cell disorder with ASCT being a promising treatment (Hayashi et al., 2014; Sidiqi et al., 2018).

IMWG criteria for amyloidosis AL

Presence of an amyloid-related systemic syndrome (e.g., renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement)

- Positive amyloid staining by Congo red in any tissue (e.g., fat aspirate, bone marrow, or organ biopsy).
- Evidence that amyloid is light-chain-related established by direct examination of the amyloid using mass spectrometry-based proteomic analysis or immunoelectronmicroscopy.
- Evidence of a monoclonal plasma cell proliferative disorder (serum monoclonal protein, abnormal free light chain ratio, or clonal plasma cells in the bone marrow).

Waldenström macroglobulinemia

Waldenström macroglobulinemia is characterized by an excess of lymphoplasmacytic cells in the bone marrow—classified as a lymphoplasmacytic lymphoma which is a non-Hodgkin lymphoma. The abnormal cell has characteristics of B-type lymphocytes and of plasma cells. This condition was first identified in Waldenström (1958). These lymphoplasmacytic cells secrete IgM, usually kappa, and rarely lambda. Most, patients have a preceding phase of IgM MGUS (Gertz, 2019), but the clonal MGUS B cells already contain the molecular signature of a malignant clone—the cells arise from $CD25^+$ $CD22^+$ low activated B lymphocytes - and there is a family history in about 4% of affected persons (Gertz, 2019). In most cases, the disease can be readily treated so that it is benign in most affected persons and considered indolent.

Most disease manifestation are due to the infiltration of the bone marrow by the malignant cell mass and complications due to high IgM. These include normocytic anemia, hyperviscosity syndrome, cryoglobulinemia, cold agglutinin disease hemolytic anemia, adenopathy (enlargement of the lymph nodes and/or hepatosplenomegaly due to accumulation of lymphocytic cells). The earliest symptom is often anemia due to bone marrow infiltration. Many cases are picked up incidentally as a result of elevated total protein or a SPE screen.

Because IgM is a pentamer hyperviscosity syndrome may occur at concentrations greater than 4 g/dL. Moreover, it is important to watch for hyperviscosity symptoms in case hyperviscosity occurs at lower concentrations of IgM. The symptoms are primarily due to shear forces that rupture venous channels and include: epistaxis, gingival bleeding, and visual changes due to retinal hemorrhage as well as central nervous system findings such as dizziness, light-headedness, and generalized fatigue. Hyperviscosity syndrome can be immediately treated with plasma exchange until the underlying cause is reduced by treating the tumor mass. The normal reference range for serum viscosity is 1.4–1.8 Centipoises (1.0 being the viscosity of water). Symptoms usually are not seen before the viscosity reaches four Centipoises (Gertz, 2019). Fig. 19 illustrates a SPE pattern from a patient with hyperviscosity syndrome.

Amyloidosis AL occurs in only about 3% of Waldenström patients (Thakral and Kanagal-Shamanna, 2016) but if amyloidosis AL or cryoglobulinemia occurs, the disease is more difficult to treat and less indolent. Cryoglobulinemia may be type I where the structure of IgM causes precipitation in cooler temperature or type two where the monoclonal IgM exhibits rheumatoid factor activity and binds to the Fc portion of IgG, causing immune complexes and precipitation at cooler temperatures. These precipitants may cause vasculitis and renal disease (Charles and Dustin, 2009). Cryoglobulins will be discussed in more detail below.

Fig. 19 IgM with Hyperviscosity syndrome.

Interference by circulating immune complexes

In some rare cases, monoclonal or polyclonal Ig may exhibit rheumatoid factor activity and form circulating immune complexes by binding to the Fc portion of polyclonal IgG. These are usually IgM but may also be IgG. These do not precipitate in the cold as cryoglobulins do, but there is some evidence that such large complexes can cause vasculitis (Levinsky).

Methodologically, these large aggregates can cause confusion in interpretation. If the RF affinity is strong, upon IFE, they may become trapped in the agarose gel and appear as monoclonal bands in all lanes. If the affinity is weaker, polyclonal or monoclonal RF may bind polyclonal IgG into an immune complex and appear as a tiny M-protein on SPE as a result of limited migration of the large complex. These lesser affinity aggregates usually stain on IFE as IgM and IgG or only IgG but both kappa and lambda. Treatment with 2-mercaptoethanol for 4 h or longer at 37 °C will break up these complexes so that interpretation is possible (Attalman and Levinson, 2000). Make a 1:10 dilution of 2-mercaptoethanol with isotonic saline (add 10 µL of the dilution to 100 µL of the patient's serum) and repeat the IFE. Fig. 20 illustrates precipitation in all IFE lanes and its solution. Fig. 21 illustrates the circumstance where a tiny restriction is seen on SPE. IFE shows staining for IgM, IgG, kappa and lambda. After treatment, it can be seen that the IgG and IgM was polyclonal.

Fig. 20 Circulating immune complex precipitate in all lanes treated with mercaptoethanol. A band on SPE appears monoclonal (arrow) but IFE shows bands in all lanes. After treatment with mercaptoethanol, fixation indicates an IgM-kappa M-protein (double arrow). Otherwise, fixation shows polyclonal kappa and lambda light chain. This indicates the IgM-kappa bound polyclonal Ig causing a large immune complex that was trapped in the gel. After treatment the immune complex was broken down. The separated complex migrated as an IgM M-protein that was kappa and polyclonal Ig. Notice there is a thin band at the origin where the sample was applied (O). This is a bit of denatured Ig that did not migrate.

Fig. 21 Polyclonal Ig appearing as monoclonal due to circulating immune complex. SPE shows a tiny band that may be monoclonal (arrow). IFE shows restricted staining in the IgM, IgG, kappa and lambda tracks (arrows). After treatment with mercaptoethanol no monoclonal is seen. There is only diffuse staining. The best interpretation is that polyclonal IgM rheumatoid factor bound polyclonal IgG and the aggregate was trapped in the gel. Treatment broke the complex down and only polyclonal migration was seen.

Cryoglobulins

Cryoglobulins are immunoglobulins or immune complexes that precipitate at temperatures below 37 °C and usually dissolve upon warming to 37 °C. Cryoglobulins have long been classified as: Monoclonal, Type I; Mixed, Type II; and polyclonal, Type III (Brouet et al., 1974). Monoclonal type I is usually associated with plasma cell dyscrasia or other hematological malignancies such as multiple myeloma or Waldenstrom macroglobulinemia. Type II may also be associated with Waldenstrom or rarely myeloma but more often mixed Type II is associated with diseases where there is a chronic infection as are Type III, especially hepatitis C (Agnello et al., 1992). Cold sensitivity in monoclonal Type I cryoglobulins seem to be dependent on the conformation of the monoclonal Ig while mixed Type II and polyclonal Type III are largely dependent on the formation of circulating immune complexes as a result of rheumatoid factor activity (Charles and Dustin, 2009). Although Type II includes a monoclonal component, when caused by chronic disease, it is not considered a true plasma cell dyscrasia. It is postulated that circulating B lymphocytes are stimulated by hepatitis C or other virus causing them initially to synthesize polyclonal IgM rheumatoid factor. However, unknown factors induce a shift to abnormal proliferation of a single clone of B cells that produces monoclonal IgM-rheumatoid factor. In fact, there is evidence that an oligoclonal phase may precede the monoclonal phase (Tedeschi et al., 2007; Charles and Dustin, 2009). This leads to type II mixed cryoglobulinemia. In Type III, the rheumatoid factor remains polyclonal.

Due to decreased solubility cryoglobulins tend to precipitate in the small vessels (venules, capillaries, arterioles) of various tissues, causing a cryoglobulins vasculitis (Shihabi, 2006). Histologically, a leukocytoclastic vasculitis secondary to vascular deposition of immune complexes is seen. This can lead to ischemia, necrosis and purpura. Especially, the kidney, skin, musculoskeletal system and peripheral nervous system may be involved (Shihabi, 2006; Dammacco and Sansonno, 2013).

Serum cryoglobulins in most patients exist in low concentrations (100–300 mg/L) as compared to concentrations (60,000–80,000 mg/L) of normal serum proteins. It is difficult to isolate such small amounts of cryoglobulins without contamination from normal serum proteins. For this reason, as much serum as can be collected is recommended for analysis. The time for analysis is long (up to 3 days) and routine quantification techniques are somewhat crude in that collection is tedious, there is no internationally accepted references, and this lack of standardization can lead to missed diagnosis of mixed type II cryoglobulinemia (Vermeersch et al., 2008). Besides, quantification is inexact.

At least 10 mL of blood should be collected in a red top tube and transported to the laboratory in a thermos container. Clot the blood in a 37–40 °C water bath. The clot should be immediately separated in a standard centrifuge for only 5 min. The serum should be immediately removed and placed in a refrigerator at about 4 °C. The sample should be examined for turbidity or a precipitate up to 72 h. If the sample remains clear, it should be reported as negative.

If turbidity is seen, the sample should be centrifuged in a refrigerated centrifuge. Turbidity due to lipid particles, non-immunoglobulin cryoprecipitates or other debris cannot be easily differentiated from cryoglobulins at refrigerated temperatures (Voma and Levinson, 2016).

Therefore, all suspect samples should be centrifuged at 4 °C. Lipoproteins will float or the serum will remain turbid. If a precipitate is found, it should be vigorously washed (Kallemuchikkal and Gorevic, 1999): Wash the pellet three times with ice cold saline and vigorous mixing (vortexing) between washes. Recentrifuge after each wash in a refrigerated centrifuge. Then, redissolve in warm saline.

The most complete way to identify and characterize cryoglobulins remains SPE and IFE (Warren, 2013). IFE will allow appropriate characterization of the precipitate (Voma and Levinson, 2016). The final pellet should be redissolved in 0.5–1 mL of warm saline with vigorous shaking and kept in a 37 °C bath until application to SPE/IFE. The amount of total protein should be

measured using a sensitive technique such as for cerebral spinal fluid protein. Generally dye binding methods are not preferred since they are more selective for some proteins (Voma and Levinson, 2016). Calculation corrections for protein should be made for volume changes from the original volume collected and SPE and IFE should be performed.

Fig. 22 illustrates a type I cryoglobulins obtained from a patient with Waldenstrom macroglobulinemia. The cryoglobulins was estimated to be about 1 g/dL. Notice there was a tiny bit of kappa and lambda staining on IFE at the origin where the sample was placed indicating a bit of nonspecific precipitate. Also, there is some albumin on PPE and tiny bit of diffuse lambda staining on IFE suggesting the sample was not sufficiently washed. Nevertheless, it is clear that it is IgM-kappa. Fig. 23 illustrates a type II cryoglobulins from a patient with chronic hepatitis C. Here, it can be seen polyclonal IgG and monoclonal IgM was identified indicating the precipitate was composed of monoclonal IgM rheumatoid factor that bound polyclonal IgG.

Fig. 22 Type I Cryoglobulins. A very large (1 g/dL) cold-precipitate from a patient with Waldenstrom macroglobulinemia was washed $3 \times$ with vigorous mixing. The precipitate was redissolved in 37°C saline and applied to electrophoresis (PPE). PPE shows densities in the gamma region and a bit of albumin. IFE show mostly an IgM restriction and co-migrating kappa. A small amount of albumin in the PPE lane indicates that the washing was not complete. Most likely the large amount of M-protein adsorbed albumin and other proteins. This is probably the reason that there is a tiny bit of lambda in the gamma region. There is also a bit of IgM, kappa and lambda at the site of sample application (o) which represents denatured protein that did not migrate. The profile clearly indicates an IgM-kappa monoclonal cryoglobulins with less than perfect washing.

Fig. 23 Type II Cryoglobulins. The precipitate was treated as in Fig. 22. A small precipitate of about 50 mg/dL was placed on electrophoresis (PPE). No albumin is seen, suggesting adequate washing. IFE shows a monoclonal IgM-kappa, polyclonal IgG and polyclonal kappa and lambda.

The effect of treatments on biomarkers

The survival of patients with multiple myeloma has been steadily improving for more than two decades (Mollee, 2009). Median survival for all patients diagnosed in the last decade from one institution improved from 29.9 months to 44.8 months. In the past, the chemotherapeutic agent melphalan and prednisolone remained the mainstay of therapy for plasma cell dyscrasias. But more recently, ASCT after high-dose chemotherapy has improved overall survival for patients with plasma cell dyscrasias and is considered the standard of care for eligible patients—age ≤ 65 years. Moreover, the newer drugs thalidomide, lenalidomide and bortezomib have been introduced (Mollee, 2009).

Bortezomib belongs to a new class of therapeutic agents called “proteasome inhibitors.” By blocking the proteasome, bortezomib causes inhibition of the nuclear factor kappa-light-chain-enhancer of the activated B cell pathway which results in myeloma cell death. Thalidomide, known as an immunomodulatory agent, is an anti-myeloma agent with many mechanisms of action, both directly against the myeloma cell, the supporting marrow microenvironment and the immune system (Mollee, 2009). Lenalidomide is an immunomodulatory agent derived from thalidomide with increased anti-myeloma potency and less likelihood of causing neuropathy, constipation and lethargy. It has been shown in randomized controlled studies to improve overall survival in patients with relapsed myeloma (Mollee, 2009). Still, most patients who achieve a good response after initial therapy eventually relapse or become refractory. Even newer proteinase inhibitors carfilzomib and ixazomib and the immunomodulatory imide drug—pomalidomide—have improved the clinical outcomes further (Nishida and Yamada, 2019).

Also, monoclonal antibodies directed against B-cells have become important therapies. Chimeric and humanized antibodies targeting CD20 on B cells have provided some relief for myeloma patients but has been more productive for use with B-cell non-Hodgkin’s lymphoma such as Waldenstrom macroglobulinemia that along with combination chemotherapy produces a greater than 90% response rate (Gertz, 2019). Also, recently ibrutinib that facilitates programmed cell death has proven very effective as a single therapy for Waldenstrom macroglobulinemia (Treon et al., 2021).

On the other hand, the humanized/human antibody drugs against CD38, daratumumab and elotuzumab have improved the clinical outcomes in plasma cell dyscrasia patients who are refractory to prior treatments including multiple myeloma and amyloidosis AL (Nishida and Yamada, 2019; Palladini et al., 2021). Since, daratumumab (DARA) and elotuzumab (Liu et al., 2020) are monoclonal antibodies, at treatment concentrations, they will appear on a majority of SPE and IFE as pseudo-M-proteins with both migrating in the gamma region. The concentration of the pseudo-M-protein is ≤ 100 mg/dL. As such, they appear as very small bands. On SPE and IFE, DARA migrates somewhat cathodal while elotuzumab migrates close to the beta-gamma region (McCudden et al., 2008; Tang et al., 2018). Thus, it is important for interpretation to know which patients are on these drugs and the interpreter must be aware of this interference, since the drugs may be mistaken for a new M-protein when a patient is being routinely monitored or for an endogenous M-protein when a patient is in remission.

If a known M-protein is migrating in a different spot, and the interpreter is aware the drugs are present, the presence of a second band that is most likely due to the drug can simply be mentioned in the report. If it is necessary to definitively identify the band daratumumab can be shifted on the gel by pretreatment of the sera with a monoclonal antibody specific for DARA, so called daratumumab-specific immunofixation electrophoresis reflex assay (DIRA) (McCudden et al., 2008; Mills and Murray, 2017). DIRA is now employed in some laboratories. More recently, DARA and elotuzumab have been removed by pretreatment with CD38 bound to beads (Liu et al., 2020).

Criteria for plasma cell responses to treatments

Successful treatment has implications for biomarkers in monitoring disease progression. Table 2 shows the IMWG criteria for response to therapy’ (found at <https://www.myeloma.org/resource-library/international-myeloma-working-group-imwg-uniform-response-criteria-multiple>), and in more detail (Durie et al., 2006).

It is apparent from Table 2 that the need for serum and urine biomarkers is as important in assessing remissions as they are in identification and prognosis of plasma cell dyscrasias since these are an essential part of the criteria. Thus, CR/sCR requires negative immunofixation on the serum and urine and normal FLC ratio. Definitions of VGPR and PR are entirely dependent on the biomarkers unless the patient is a non-secreter. This is also true for no change/stable disease. Serum and urine M-protein levels and FLC levels are biomarkers for progressive disease relapse from CR.

Successful therapy has also led to peculiar patterns that add difficulty to interpretations on SPE and IFE. Treatment with newer agents as compared to chemotherapy and especially with autologous transplantation has resulted in an increase incidence of oligoclonal banding (Tovar et al., 2013) on SPE, similar to that shown in Fig. 16B. The oligoclonal bands may be only kappa or lambda but are more often both kappa and lambda on IFE (Singh, 2017) (Fig. 16B). The oligoclonal pattern may last for up to 1 or 2 years or be shorter lived (Tovar et al., 2013). Generally, this pattern appears to be a good prognostic sign and these patients seem to have longer remissions (Tovar et al., 2013; Singh, 2017). The mechanisms underlying the development of oligo-clonal bands remains unsettled (Tovar et al., 2013; Singh, 2017), although it seems the most likely explanation is that a bone marrow recovering from successful treatment would give rise initially to a few clones prior to polyclonal expansion.

If the oligoclonal banding is only kappa or lambda a difficulty can arise if the original monoclonal was of the same light chain type, since it will be unclear whether or not the malignant clone gave rise to the oligoclonal banding. In this case, it is likely it was

Table 2 Criteria for plasma cell responses.

<i>Response</i>	<i>IMWG criteria</i>
Stringent Complete Response (sCR)	CR as defined below plus normal FLC ratio and absence of clonal cells in bone marrow by immunohistochemistry or immunofluorescence
Complete Response (CR)	Negative immunofixation on the serum and urine and disappearance of any soft tissue plasmacytomas and <5% plasma cells in bone marrow
Very good partial response (VGPR)	Serum and urine M-protein detectable by immunofixation but not on electrophoresis or >90% reduction in serum M-protein plus urine M-protein level <100 mg/24 h
Partial response (PR)	>50% reduction of serum M-protein and reduction in 24 h urinary M-protein by >90% or to <200 mg/24 h If the serum and urine M-protein are unmeasurable, a >50% decrease in the difference between involved and uninvolved FLC levels is required in place of the M-protein criteria If serum and urine M-protein are not measurable, and serum free light assay is also not measurable, >50% reduction in plasma cells is required in place of M-protein, provided baseline bone marrow plasma cell percentage was >30% In addition to the above listed criteria, if present at baseline, a >50% reduction in the size of soft tissue plasmacytomas is also required
MR	NA
No change/Stable disease	Not meeting criteria for CR, VGPR, PR, or progressive disease
Plateau	NA
Progressive disease	Increase of >25% from lowest response value in any one or more of the following: • Serum M-component and/or (the absolute increase must be >0.5 g/dL) • Urine M-component and/or (the absolute increase must be >200 mg/24 h) • Only in patients without measurable serum and urine M-protein levels; the difference between involved and uninvolved FLC levels. The absolute increase must be >10 mg/dL • Bone marrow plasma cell percentage; the absolute percentage must be >10% • Definite development of new bone lesions or soft tissue plasmacytomas or definite increase in the size of existing bone lesions or soft tissue plasmacytomas • Development of hypercalcemia (corrected serum calcium >11.5 mg/dL or 2.65 mmol/L) that can be attributed solely to the plasma cell proliferative disorder
Relapse	Clinical relapse requires one or more of: Direct indicators of increasing disease and/or end organ dysfunction (CRAB features). It is not used in calculation of time to progression or progression-free survival but is listed here as something that can be reported optionally or for use in clinical practice • Development of new soft tissue plasmacytomas or bone lesions • Definite increase in the size of existing plasmacytomas or bone lesions. A definite increase is defined as a 50% (and at least 1 cm) increase as measured serially by the sum of the products of the cross-diameters of the measurable lesion • Hypercalcemia (>11.5 mg/dL) [2.65 mmol/L] • Decrease in hemoglobin of >2 g/dL [1.25 mmol/L] • Rise in serum creatinine by 2 mg/dL or more [177 mmol/L or more]
Relapse from CR [To be used only if the end point studied is Disease Free survival (DFS)]	Any one or more of the following: • Reappearance of serum or urine M-protein by immunofixation or electrophoresis • Development of >5% plasma cells in the bone marrow • Appearance of any other sign of progression (i.e., new plasmacytoma, lytic bone lesion, or hypercalcemia)

not the malignant clone but watching and waiting is the best solution. If the oligoclonal banding is of a different type or both kappa and lambda, one can be reasonably certain it is a true oligoclonal response unrelated to the malignant clone.

Conclusions and summary

In the above discussions a good deal of detail was presented in terms of electrophoretic patterns and methodologies, especially descriptions of the methods and interpretations. Some historical content, weaknesses of the techniques and exact recommended collection and procedural processes were also discussed. The basis of humeral immunology was discussed to improve the understanding of where, why and how monoclonal gammopathies develop. Besides there was an over view of associated workup for diagnosing, monitoring progress and therapy and defining status of persons with or suspected of having monoclonal gammopathies. Also, some information on treatments was presented to put the concepts in a more complete perspective. The article also focused on why these methods are implicit in diagnosing, monitoring, treating and defining status of these conditions. In conclusion, the methods discussed are important instruments for following biomarkers in diagnosing, monitoring and treating monoclonal gammopathies.

The polarities are indicated in all the electrophoretograms. In IFE Figures, the wells near the bottom are control wells where sample is added along with antisera to ensure the reaction occurred. On IFE plates IgG, IgM, IgA or G, M, A indicates fixation for IgG, IgM and IgA heavy chain proteins in the lane just below. Similarly, kappa (κ) and lambda (λ) indicate fixation for the appropriate type of light chain.

Introduction

Until the end of the 1970s replication of chromosomal end was a biological issue that had yet to be explained. The one lagging strand could not be copied if the process of polymerases' action previously described was considered. This dilemma was called "end replication problem" (Olovnikov, 1971; Watson, 1972).

In 1978, this "problem" began to be resolved by assessing the ends of *Tetrahymena thermophila* chromosomes, which contained six TTGGGG bases sequences, repeated 20–70 times (Blackburn and Gall, 1978). In 1985, Greider and Blackburn identified an enzyme capable to extend those telomeric sequences (Greider and Blackburn, 1985) described as "terminal transferase" activity; the enzyme capable of maintaining telomeric length was called "telomerase" (Greider and Blackburn, 1987, 1989). Furthermore, mammalian telomeres have been described as tandem repeats of TTAGGG_n DNA sequences associated with the so-called shelterin complex, consisting of six proteins. Thus, the terminal structure of the telomeres conforms to a loop-like structure protecting the chromosomal ends (Greider, 1991; de Lange, 2005). Since the "end replication problem" was solved by description of telomerase-activity, a number of techniques to study telomere-length, especially in aging cells and diseases have increased in numbers, sensitivity and resolution. These approaches are applied e.g., to monitor neoplastic cells, being targeted by new specific drugs to prevent telomere extension, as the latter promotes cells immortality (Norton et al., 1996; Herbert et al., 2005; Relitti et al., 2020).

In this article, the techniques by which telomeric regions have been studied along the decades are reviewed in terms of their stepwise contributions they brought into the area (see Fig. 1). In the following sections, each of these techniques for studying the length of human telomeres is presented and discussed and correlated with scientific impact, advantages and disadvantages.

Fig. 1 Main telomere length measurement methods timeline. *TRF*, telomere restriction fragment; *Q-FISH*, quantitative fluorescence in situ hybridization; *qPCR*, quantitative polymerase chain reaction; *STELA*, single telomere length analysis; *PRINS*, primed in situ hybridization; *HT*, high-throughput; *MMqPCR*, monochrome multiplex quantitative polymerase chain reaction; *U-STELA*, universal single telomere length analysis; *TESLA*, telomere shortest length assay; *DNAmTL*, DNA methylation-based estimator of telomere length. Telomere restriction fragment (TRF)/Southern blot

Most molecular genetic methods being applied for telomere length measurements are inspired by double helix DNA structure. Scientists took advantage of the DNA-characteristic being able to in vitro strand dissociation (denaturation) and re-association (renaturation or hybridization).

Southern blot was technique proposed in the beginning of the recombinant DNA-era (Southern, 1975) as the first method able measure telomere length (TL) (Moyzis et al., 1988; Allshire et al., 1989); later on, this approach was renamed as Telomere Restriction Fragment method (TRF).

First: The protocol: Determining DNA integrity

Prior to necessary restriction digestion of whole genomic DNA applied in TRF, a sample of 1 µg of each DNA-sample should be electrophoresed in an agarose 0.8–1% gel to verify its integrity; a large, high molecular weight band without smear should be the result.

DNA-sample is applied to the gel well with 1:1 volume of loading buffer (0.05% bromophenol blue, 0.05% xylene cyanol, glycerol 50%). Electrophoresis buffer can be either buffer Tris-acetate—1xTAE (0.04 M Tris-acetate, 0.001 M EDTA, pH 8.0) or Tris-borate buffer—1xTBE (Tris base 0.09 M, acid boric 0.09 M, EDTA 0.002 M, pH 8.0). After electrophoresis (1 or 2 h, room temperature, 60–100 V), the gel is stained with ethidium bromide. Besides, there are others chemicals able to label DNA, like SYBR Green I.

Second: DNA digestion

The genomic DNA-sample is fragmented by two restriction enzymes (type II): *HinfI* and *RsaI*. These restriction enzymes type II were discovered in bacteria and cleave double-stranded DNA at specific recognition sites of 4 or 6 base pairs (bp) in length.

The digested DNA is separated on a 0.6–1.0% agarose gel in 1xTAE or 1xTBE buffer. Electrophoresis must be performed at low speed, preferentially overnight. It is necessary to load in a separated well a DNA molecular marker (e.g., 1 kb and λ DNA/*HindIII* ladder) with known DNA fragment sizes in one of the wells as for co-migration in the gel. Later the size-standard will be necessary to determine TL in kilobasepairs (kb). Finally, the gel is stained with ethidium bromide to confirm DNA digestion (a smear is visible) and that small DNA-fragments have not been lost during electrophoresis.

Third: The blotting

Gel is now immersed in denaturation solution (0.5 M NaOH, 1.0 M NaCl) for 30 min, room temperature with slow shaking to obtain single stranded DNA. Then, the gel is transferred to a neutralization solution (1 M Tris-HCl and 1.5 M NaCl, pH 8.0) for 30–60 min under slow shaking.

The blotting system is quite simple and resembles a multilayer sandwich. To start, cover a surface with plastic wrap (e.g., PVA) or glass plate, lay on it a stack of paper-towels, then a piece of filter-paper, then the piece of the nitrocellulose-membrane, the wet gel and cover all of it with plastic film. Continuing, put a glass plate on the top and then a weight on it, and let it go overnight. This way of DNA transferring is known as downward capillary transfer, that is different (inverted) from the original Southern Blot (Green and Sambrook, 2012). Afterwards, nitrocellulose-membrane has taken up the DNA-sample and can be air-dried to fix the DNA.

Fourth: Preparing the probe

The probe is a polymer of 3 or 4 TTAGGG repeats that can be labeled by λ -P³² ATP or DIG (digoxigenin) as for the chemo-luminescence revelation method. The DNA molecular marker should be labeled in the same way. Nowadays, the telomeric DNA probe and the molecular marker labeled by DIG can be ordered from many companies; however, if necessary, isotope labeling can be performed also in-lab. In this case, the telomeric probe can be labeled by the enzyme T4 polynucleotide kinase, originally from a bacteriophage, which transfers the λ -phosphate of λ -P³² ATP, into the 5'-termini of DNA. As for the molecular marker, the Nick translation method should be applied, in which the *Escherichia coli* DNA polymerase I incorporates radiolabeled nucleotides in double stranded DNA after DNase has set single strand breaks = nicks (Temsamani and Agrawal, 1996). The T4 polynucleotide kinase is commercially available as well as Nick translation kits.

Fifth: Hybridization with telomeric probes

Prehybridize and the nitrocellulose-membrane by immersing in prehybridization or hybridization solution for 15 min at 42 °C. Most commonly, the hybridization solution contains: 3–10 × SSC, 2–3 × Denhardt's solutions, 0.3 M NaCl, 10 mM Tris-Cl (pH 8.0), 1 mM EDTA, 0.1% SDS and 100 µg/mL yeast tRNA. Denhardt's solution is composed of 1% Bovine Serum Albumin (BSA), 1% Ficoll, 1% Polyvinylpyrrolidone (PVP) in water. 1 × SSC solution is composed of NaCl 0.15 M and 0.015 M Na₃citrate (pH 7.0).

Hybridization occurs in a tube mounted in a rotating hybridization oven after adding of the telomeric DNA probe. If the molecular marker was in-lab labeled by P³² labeled, it should be previously denatured (95 °C for 3 min), and added to the hybridization solution about the same time as the telomeric probe. Hybridization takes place overnight.

Sixth: Post hybridization and TL analysis

The hybridization is stopped by immersing the nitrocellulose-membrane in washing solution (2 × SSC, 0.1% SDS), two times, 15–30 min, each, followed by two times washing with 2 × SSC, 10 min, each; perform all washes under slow shaking. Normally, washing is done at room temperature, but if later-on a background shows up, then it is recommended to increase the temperature of the washing up to 60 °C.

To visualize the results TRF nitrocellulose-membrane is exposed to an X-ray film in a cassette, usually in cooling conditions. All the film's manipulation and developing takes place in a darkroom with a safelight. If the probe is labeled by P³², the film can be exposed, wrapped in PVA plastic, from overnight to a few days depending on the decay of the isotope (P³² half-life is 14 days). If it is labeled by DIG, the exposure depends on the emission of the chemiluminescent light that is a result of ligations and chemical reactions, beginning with antidigoxigenin antibody conjugated with alkaline phosphatase. Then, the chemiluminescent substrate for alkaline phosphatase (CDP-Star[®]) is added allowing the detection of alkaline phosphatase.

After exposure and film development, the image can be scanned by a commercially available imaging device, e.g., Image Quant[®] software (Molecular Dynamics). In comparison to the molecular marker the TL is determined (in kb = bp × 1000). Generally, human telomeres are composed of 10–15 kb of TTAGGG repeats (Fig. 2) (Allshire et al., 1989; Fernández-Marcelo et al., 2016), but an 80 years-old person can show telomere as short as 1.2 kb (Kimura et al., 2010).

Notes

- One variation of the TRF technique is the in-gel hybridization that requires drying the gel to perform the hybridization on it (Bryan et al., 1995; Fouquerel et al., 2019). The gel can be dried at 50–60 °C for 2 h, under vacuum, and then denatured.
- Since the beginning there were controversies about what is the best set of restriction enzymes to measure TL by TRF. Depending on the set of restriction enzymes used, the TL can result in a difference as much as 1 kb (Kimura and Aviv, 2011). In the first works of TRF the authors also tested other enzymes such as *SAU3A*, *MnII*, and *HphI* (Moyzis et al., 1988; Allshire et al., 1989; Kimura and Aviv, 2011). Other protocols apply alternative combinations of restriction enzymes for digesting the telomeric DNA, such as *MseI/NdeI*; or *Bfal/CviAII/MseI/NdeI*. The use of these combinations can minimize the inclusion of subtelomeric regions containing variations (polymorphisms) in the telomeric repeats (Lai et al., 2018). A combination of *HhaI*, *HinF1*, *MspI*, *HaeIII*, *RsaI*, and *AluI* was also recommended (Mender and Shay, 2015). The digestion by different restriction enzymes (sometimes from different suppliers) may require an in-lab universal restriction buffer. The universal buffer (5 ×) is composed of 0.1 M Tris-Cl pH 8.0, 0.25 M NaCl, 0.05 M MgCl₂ and 0.5 mg/mL lysozyme (Fanning et al., 1980).

Fig. 2 Results of a representative X-ray film for TL analysis from five colorectal cancer patients (Pt) in tumor tissues (T) and their paired non-tumor samples (N). C, positive control (TeloTAGGG™ Telomere Length Assay, Cat No. 12209136001). MWM, DNA molecular weight marker (in kb). Figure and caption taken from Fernández-Marcelo T, Sánchez-Pernaute A, Pascua I et al. (2016) Clinical relevance of telomere status and telomerase activity in colorectal cancer. *PLoS One* **11**(2): e0149626.

- Blotting takes place driven by capillarity of aqueous solution, however electric or vacuum transfer equipment can be applied to speed up procedure to 1 h (Allshire et al., 1989; Green and Sambook, 2012). Also, downward capillary transfer of DNA using a transfer solution through a paper bridge containing 3 M NaCl and 8 mM NaOH in 1 h (Chomczynski, 1992) has been reported.
- Membranes are made besides from nitrocellulose of neutral nylon or charged nylon. The last one is considered to be the best (Green and Sambook, 2012).
- A simple in-lab made hybridization solution targeting high abundance sequence is composed of 6xSSC and 0.05% BLOTTO. BLOTTO is a mixture of 5% non-fatdried milk dissolved in water containing 0.02% sodium acid (Sambrook et al., 1989).

Nowadays, it is possible to buy kits with all the necessary reagents to perform TRF, e.g., TeloTAGGG Telomere Length Assay Kit (Roche), which applies chemiluminescent detection.

Dot and slot blotting for TL

Dot-blot is semi-quantitative method to estimate the presence of specific DNA sequences based on hybridization. DNA samples are spotted next to each other on a filter (nitrocellulose or nylon) in dots of uniform diameter. The filter is subject to denaturing conditions and then hybridized with a probe. For quantification, a sequence of diluted DNA with known concentrations are similarly spotted and used for comparison. The biggest advantage of dot-blot method is that it can be applied to a large number of DNA samples (Kafatos et al., 1979), being faster and cheaper than a TRF, since no electrophoresis and DNA transfer are required.

Kimura and Aviv (2011) applied the dot-blot method to measure TL, requiring small amounts of DNA (~20 ng/assay). The authors evaluated the DNA content of the sample on the blot by SYBR Dx DNA Blot Stain (S-7550, Invitrogen). The blot was hybridized with a DIG-labeled telomeric probe and the ratio of telomere repeats/DNA (T/Dx) corresponded to the amount of the repeats per unit DNA. A Bio-Dot Microfiltration Apparatus (BioRad) was used for the DNA samples blotting.

Single TL analysis

Single TL analysis (STELA) is a PCR-based technology combined with Southern Blot hybridization; it was developed by Baird et al. (2003) for measuring TLs on individual chromosomes. The technique was first described to track XpYp telomeric length, being latter adopted for autosomal human telomeres, such as 2p, 11q, 12q, and 17p (Baird et al., 2003; Britt-Compton et al., 2012; Lin et al., 2010; Xing et al., 2009). STELA is able to reveal telomeres short enough for being subject to fusion events and induced genomic instability, thus being a useful tool to provide relevant clinical information (Capper et al., 2007; Lin et al., 2010; Garcia-Martin et al., 2017).

Standard STELA assay includes: (a) extraction of genomic DNA followed by digestion with restriction enzymes (e.g., *EcoRI*); (b) a telorette linker, represented by seven bases complementary to the G-rich 3' overhang followed by a 20-nucleotide non complementary tail; (c) a teltail primer, similar to telorette sequence, which specifically recognizes the telorette; (d) a chromosome-specific primer, designed for the subtelomeric region; (e) detection of STELA products by gel electrophoresis and Southern hybridization with a radiolabeled probe to produce telomere band images (Baird et al., 2003).

Although STELA is a useful approach for measuring the dynamics of telomere shortening, the method has some limitations since specificity of proximal primers is required and this only applicable for a small subset of chromosomal ends; therefore, investigations on different telomere shortening rates between chromosomes and the triggering of cellular senescence are limited (Leach et al., 2004; Martin-Ruiz et al., 2004; Britt-Compton et al., 2006; Bendix et al., 2010). Based on this, the Universal STELA (U-STELA) assay, a STELA variation technique described by Bendix et al. (2010) was designed to measure any TL regardless its location, and thus detect telomeres that are extremely short and potentially drive senescence processes (Cagsin et al., 2020). Despite this, U-STELA cannot efficiently detect longer telomeric stretches (above 8 kb) (Bendix et al., 2010). Another STELA-based technique is the high-throughput STELA (HT-STELA), which was developed to improve this technology and applied to predict for outcome to fludarabine, cyclophosphamide, rituximab (FCR) based therapy (Norris et al., 2019).

Telomere shortest length assay

Telomere shortest length assay (TeSLA) is a sensitive method developed for TL measurement able to accurately detect telomeres ranging from <1 kb to 18 kb (Lai et al., 2017). This technique needs an image-processing software to detect and calculate TL after Southern blot, being a more informative assay than TRF (Lai et al., 2017; Zhang et al., 2021).

Molecular cytogenetics-based analyzes

Molecular cytogenetics is a primarily single-cell oriented approach, by which TL measuring can also be realized. The field of molecular cytogenetics is based on two approaches: Fluorescence in situ hybridization (FISH) (Weise and Liehr, 2017a) and primed in situ hybridization (PRINS) (Charlieu and Pellestor, 1997). Both methods are suited to detect telomeres and to measure their lengths.

Quantitative fluorescence in situ hybridization (Q-FISH)

Quantitative fluorescence in situ hybridization (Q-FISH) is rather based on a standard FISH applying peptide nucleic acid (PNA) telomere oligonucleotide probe to cytogenetically worked up material containing interphases and/or metaphases from different sources. Quantitative hybridization to telomere repeats is achieved using conditions that allow the labeled (CCCTAA)₃ PNA probe to hybridize to TTAGGG repetitive sequences. The PNA probes are synthetic, particularly resistant and better hybridizing to DNA than other synthetic probes. Q-FISH can only be evaluated with appropriate digital image software able to capture pictures under defined conditions and adequate quantification of fluorescence signals. Herby it is implied that TL is directly proportional to the acquired fluorescence intensity (Joksic et al., 2017). Best results are obtained when the PNA telomere oligonucleotide probe is used together with a corresponding centromeric probe as control and standard. Besides fluorescence beads of defined size can be used as internal controls (Joksic et al., 2017).

Metaphase-oriented Q-FISH

In Q-FISH on metaphases a resolution of 200 base pairs per single cell can be achieved for TL determination (Slijepcevic, 2001); also, intra- and inter-chromosomal TL variation can be accessed (Lansdorp et al., 1996; Poon and Lansdorp, 2001). The main restriction of this approach is the limited number of tissues from which metaphase chromosomes can be prepared—i.e., peripheral blood lymphocytes, bone marrow cells, (skin) fibroblasts and tumor cells (Weise and Liehr, 2017b). An interesting variant of the standard Q-FISH in metaphases is the so-called Replicative Detargeting FISH (ReD-FISH), which enables studies of replicative patterns of telomeres on different, individual chromosomal arms (Rubtsov and Zhdanova, 2017).

Slide preparations with metaphasic cells is traditionally based on the so-called air-drying method. Apart from peripheral blood lymphocytes, where cells need to be growth stimulated by phytohemagglutinine, all other suited tissues grow without such stimulation in cell culture. After corresponding culturing time (72 h for lymphocytes; ~14 days or longer for fibroblasts) cells are arrested in metaphase by colchicine or colcemid. Cells are harvested, centrifuged and subjected to hypotonic treatment with 0.075 M KCl (37 °C for 20 min); thereby chromosomes are separated from each other within the cell. In between all afterwards mentioned steps cells are pelleted by centrifugation (1000 × g for 5 min). Cells are deadened by adding of Carnoy's fixative (3:1 methanol:glacial acetic acid), and washed three times in fresh fixative (e.g., 5 mL each). After last centrifugation, supernatant is discarded and pellet is diluted in 100–500 µL of remaining fixative. The suspension is dropped on a slide and air dried. During this step first methanol evaporates; the remaining acetic acid acquired water from surrounding air, which leads to chromosome swelling and spreading. Thus, chromosome preparation is dependent of humidity. Slides must be stored at room temperature (RT) for at least 12 h before use in FISH. Before FISH, slides are dehydrated in an ethanol series (70%; 90%; 100%, for 3 min, each) (Weise and Liehr, 2019).

For FISH dry slides are first incubated in $100\text{ mL } 2 \times \text{SSC}$ for 1 min at RT in a coplin jar and then in a pre-warmed pepsin-buffer (37°C) with $1 \times \text{PBS}$. Afterwards, slides are washed in $1 \times \text{PBS}/\text{MgCl}_2$ at RT (5 min) with gentle agitation, whereby MgCl_2 blocks the enzymatic activity of pepsin. A formalin-buffer may be used for 10 min at RT with gentle agitation to achieve a better chromosome structure after FISH. Pretreatment is finished by washing slides in $1 \times \text{PBS}$ for 2 min (RT) with gentle agitation, dehydration by an ethanol series (70%, 90%, 100%, 3 min each) and air drying.

To do FISH DNA fixed on slides and probe-DNA need to be single stranded. Thus, DNA on slides needs to be denatured: per slide $10\text{ }\mu\text{L}$ of denaturation solution (70% (v/v) deionized formamide, 10% (v/v) filtered double distilled water, 10% (v/v) $20 \times \text{SSC}$, 10% (v/v) phosphate buffer) are added and covered with coverslips. Slides are incubated on a heating plate for 3 min at 75°C . Afterwards, coverslips are removed (e.g., by forceps) and transferred to a coplin jar filled with 70% ethanol (4°C) to conserve target DNA as single strands. Afterwards dehydrate the slides again in ethanol series (70%, 90%, 100%, 4°C , 3 min each), and air dry.

For DNA-probe hybridization, apply the single stranded manufactured probe FITC-(CCCTAA)₃ PNA on the slide. It is commercially available as ready-to-use in a hybridization solution (70% formamide, 1 mg/mL blocking reagent (Roche), 10 mM Tris-HCl pH 7.2). Add $10\text{ }\mu\text{L}$ of probe mix to the denatured slide, cover with a coverslip, seal it with rubber cement and incubate the slide overnight at 37°C in a humid chamber (Li et al., 2017).

Remove rubber cement by forceps, and start posthybridization-washes by placing the slides in a coplin jar with $4 \times \text{SSC}/0.2\%$ Tween (RT), and allow coverslips to slide off. Incubate slides 2 min in $0.4 \times \text{SSC}$ ($56\text{--}62^\circ\text{C}$) followed by 1 min in $4 \times \text{SSC}/0.2\%$ Tween (RT). The slides are mounted with antifade reagent VECTASHIELD with DAPI (4, 6-diamidino-2-phenylindole) and covered with a coverslip.

Under fluorescence microscope, chromosomes show blue color (DAPI) counterstain. The TL-specific probe is usually red due to Cy3 labeling. Capture images and analyzes can be done by appropriate software and tools. As above mentioned, TL is directly related to its integrated fluorescence intensity, as PNA probes are assumed to hybridize quantitatively to telomeric repeats. If TFL-TELO software is used, results are expressed in telomere fluorescence units (TFU), with each unit corresponding to 1 kb of telomere repeats (Joksic et al., 2017). It is recommended to analyze at least 15–20 metaphases per sample to obtain reliable results.

Interphase-oriented Q-FISH

Q-FISH in interphase nuclei is possible from whatever tissues, where cellular nuclei can be prepared from. This includes all afore mentioned preparations from culturable tissues, which contain besides metaphases always tons of interphase cells (González-Suárez et al., 2000). Additionally, interphase cells from archived material like formalin-fixed paraffin embedded (FFPE) or cryofixed tissues, but also cells e.g., from buccal mucosa, hair roots or urine derived bladder cells. While in metaphase FISH it is principally possible to study specific chromosomal ends, this is excluded in interphase-oriented Q-FISH; here only 92 telomeres per cell can be measured per cell. Interphase-oriented Q-FISH is technically done the same way as described before for metaphase oriented one, but can be also applied to cell-type specific analysis when combined with immunohistochemical staining, as well as it can be automatized (Canela et al., 2007; Vera and Blasco, 2012).

In order to measure TL in a larger number of cells, a high-throughput (HT) Q-FISH platform was developed combining the labeling of telomeres in interphase nuclei, using the same PNA probe against telomeric DNA as mentioned earlier. However, the cells are cultivated in clear bottom black-walled 96-well plates. After FISH, the wells are filled with mounting medium, and the plates can be stored if necessary, overnight at 4°C until quantitative image acquisition (Canela et al., 2007; Alda et al., 2016). TL values are analyzed using individual telomere labeled spots. The results can be observed in histograms with up to 60,000 telomeres (Quintela-Fandino et al., 2017) (Fig. 3).

Recently, a modification of interphase HT Q-FISH called Telomere Analysis Technology (TAT[®]) was reported, using automated procedures on 384-well plates for large-scale studies on fixed lymphocytes. TAT includes HT imaging and software workflows (Pedro et al., 2020).

Flow-FISH

FISH is done usually on cells fixed to a slide surface (Weise and Liehr, 2017a). However, there are also variants to perform the procedure in suspension (S-FISH) (Steinhaeuser et al., 2002). Accordingly, Q-FISH can be performed in suspension—the hybridized cells are here analyzed in a flow cytometer. Overall, as in normal interphase Q-FISH, an average TL is determined (Hultdin et al., 1998). Like in S-FISH flow-FISH allows insights into nuclear architecture of the studied cells (Samassekou et al., 2010). This method estimates the average TL based on the average telomere content (quantity of telomere repeats) of single cells, expressed as mean fluorescence intensity and translated into kb based on its correlation with TRF analysis. Of note, it also allows the measurement of telomere content in specific cell subsets (Baerlocher et al., 2002).

To ensure the accuracy of experiment, some details are important to observe (Baerlocher et al., 2006): (a) a two-laser flow cytometer is recommended; (b) to guarantee the sensitivity of the derived fluorochromes, validation by calibration beads is necessary; (c) it is extremely important to calibrate the emission channel used to collect fluorescence from the hybridized PNA probe, in order to distinguish the lowest signal levels, in addition to eliminating background signals, or autofluorescence; (d) it is ideal the use of hybridization buffer based on the components: 5% dextrose/10 mM Hepes and 0.1% BSA; (d) to acquire the

Fig. 3 (A) HT Q-FISH: pictures from a patient with most telomeres below 3 kb (left) and a patient with most telomeres above 3 kb (right). (B) Histograms depicting the telomere determinations from patients shown in (A). Each bar represents the number of telomeres determined within 2 TLs in 0.5 kb-increments per sample. The number of telomeres measured per sample is greater than 60,000. Figure and caption taken from Quintela-Fandino M, Soberon N, Lluch A et al. (2017) Critically short telomeres and toxicity of chemotherapy in early breast cancer. *Oncotarget* 8(13): 21472–21482.

data on the cytometer, always keep the sample on ice, as long as possible; (e) acquire 10,000 events of cells without and with the PNA probes. Adjust regions and compensation settings if needed.

Primed in situ (PRINS) based analyzes

Primed in situ hybridization is a variant of in situ PCR. This technique is based on the in situ annealing of synthetic oligonucleotides (CCCTAA)₇ to complementary nucleic acid sequences (telomeric DNA), followed by primer extension in the presence of a hapten- or fluorochromelabeled nucleotide (Bolzán and Bianchi, 2006). The telomeric fluorescence signal is generated by the incorporation of a labeled nucleotide into the newly synthesized telomeric DNA. PRINS can be performed using telomere-specific primers on slides with either metaphases or interphases. The obtained results cannot be distinguished from that of metaphase- or interphase-oriented Q-FISH. Also, a centromere may be labeled by PRINS as internal control in parallel to the telomeres. The major advantage of PRINS compared to Q-FISH is the length of the procedure itself. While Q-FISH needs an overnight hybridization step, PRINS-labeling is completed within 1–2 h (Charlieu and Pellestor, 1997).

For PRINS, the slides are treated with RNase for 1 h at 37 °C, washed in PBS (pH 7.4) and then subjected to the ethanol series (70%, 85% and 100%) for dehydration. The reaction mixture contains 0.2 mmol/L primers Telo (CCCTAA)₇, 0.04 mmol/L biotin-11-dUTP, 10 × reaction solution, and 1 U Taq polymerase. Final reaction mix is pipetted on the treated slide, mounted with a coverslip and sealed with rubber cement. The slide is then placed on pre-heated block at 94 °C for 5 min and further at 60 °C for 30 min. The reaction is stopped by transferring the slide to stop buffer (50 mmol/L NaCl and 50 mmol/L EDTA, pH 8.0) at 60 °C for 5 min, and next to stop buffer (50 mmol/L NaCl and 50 mmol/L EDTA pH = 8.0) for 7 min. Before detection of biotin, the slides are dehydrated through an ethanol series (70%, 85% and 100%) and then treated with a blocking solution (3% BSA, 4 × SSC, 0.05% Tween 20) at 37 °C for 30 min. The during PRINS reaction to target incorporated DNA, biotin-labeled nucleotides are detected with avidin-FITC. This is done by adding avidin-FITC resolved in blocking solution to the slide at 37 °C for 45 min in a humid chamber. The reaction is stopped by washing three times at 45 °C for 3 min in 4 × SSC, 0.05% Tween 20. After final wash, the slide is air-dried, counterstained with solution of propidium iodide at room temperature for 2 min and washed twice in distilled water. The evaluation can be done as describe for Q-FISH (Koch et al., 1995; Hong Tian et al., 2011).

Quantitative polymerase chain reaction (qPCR) and variations in TL measurement

There are several methods for estimating TL, however qPCR method is the most economical one and uses only small amounts of DNA. qPCR is a derivation of the standard PCR techniques established by Mullis in 1985 and used to quantify DNA based on the emission of fluorescence during each cycle of the PCR-reaction (Mullis, 1990). The methods used in this technique are based on fluorescent dyes binding to double-stranded DNA (Sybr Green assay) or specific probes (TaqMan probes). Results can be generated as absolute values, as there is a comparison between the total number of copies of the PCR product with a standard curve; or they may be relative, when the average of the target gene signals are compared to a control gene. In the later model, a Ct value is calculated, which corresponds to the number of cycles in which the emitted fluorescence signal reaches a significant threshold (exponential phase) (Fig. 4) and it is possible to identify the specific amplified DNA fragments using an analysis of their melting temperature by comparing the dissociation curves of the analyzed samples (Fig. 5).

Fig. 4 The genomic DNA is quantified by qPCR. This figure shows an amplification curve demonstrating the Ct value corresponding to the cycle number at which the PCR curve crosses the threshold. The legend shows each sample analyzed in duplicate.

Fig. 5 Melting curve. The legend shows each sample was analyzed in duplicate.

In 2002, Cawthon introduced the qPCR technique as a tool for measuring the relative TL by comparing the TL averages in each sample and in a reference DNA sample in a ratio of telomere repeat copy numbers to single copy gene copy numbers (Cawthon, 2002). Here telomeric sequences and single copy gene PCRs are performed on separate plates. Two mixtures of PCR reagents are prepared, each using its primer pair, one with T (telomeric DNA) and the primer pair S (single copy gene) which serves as a basis for

normalizing the telomere's quantitative PCR signal. Thus, the ratio (T/S) between these averages would express the relative TL. Cawthon performed the reproducibility test of T/S ratio measurement (mean of the standard deviation = 9.4%) and compared the results of measuring TL between the means by qPCR and TRF ($R^2 = 0.677$; $P = 1.492 \times 10^{-24}$). Since then, this technique has been used widely in numerous studies that evaluate the TL in different applications.

A few years later, O'Callaghan et al. (2008) modified the technique first described by Cawthon. The author introduced an oligomer pattern containing 84 bp (approximately 14 repetitions of "TTAGGG") in length and a single copy gene (36B4–75 bp in length) that acts as a control for amplification. The data generated in kb/reaction has an ability to express the absolute value of the TL per human diploid genome instead of the relative quantification. In these articles, researchers demonstrated their protocols for several cell types, such as buccal cells and lymphocytes. The data obtained were compared to the TRF method and demonstrated a stronger correlation ($R^2 = 0.88$, $P < .0001$) (O'Callaghan and Fenech, 2011). Several research groups have applied this technique, absolute telomere length (aTL) using quantitative real-time polymerase chain reaction, as a basis for their analysis of diseases, psychological disorders and cancer risk associated with TL (Zeng et al., 2017; Chang et al., 2018; Jin et al., 2018; Mehrez et al., 2019; Ropio et al., 2020).

After developing a singleplex qPCR assay, Cawthon (2009), optimized the technique and created a multiplex qPCR model that optimized the accuracy, throughput and reduced the costs of the previously described technique. The purpose of this technique, Monochrome Multiplex Quantitative Polymerase Chain Reaction (MMqPCR), is to allow signals from any amplicons to be collected in a single run on the thermal cycler, both from the target sequence of interest (74 °C provided the Ct values for the amplification of T) and from the reference gene sequence (88 °C provided the Ct values for the amplification of S), where the average T/S ratio would estimate the relative TL per cell. In this work, Cawthon compared the results obtained through MMqPCR with results from TRF for validation, and showed a stronger correlation with different techniques ($R^2 = 0.844$), which demonstrated a greater correlation compared with data from the same samples by singleplex qPCR method ($R^2 = 0.677$).

In 2014, Kibriya et al. described an approach to determined TL based on fluorescence emitted by specific probes in the Luminex platform, where probes for telomere (T) and reference gene (R) are tested in a single well. The hybridization stage occurs with the capture of the target DNA sequence with specific sequence probes. Then, amplifiers that promote several hybridization events through biotinylated probes are added and, subsequently, they emit fluorescence signals when linked to Streptavidin R-Phycoerythrin (SAPE). The intensity of fluorescence signals is read on the Luminex platform and this technique has been accepted as an attractive alternative to conventional methods to measurement of TL such as qPCR ($R^2 = 0.70$ – 0.83) and Southern Blot ($R^2 = 0.74$) (Kibriya et al., 2014, 2016; Pierce et al., 2016). Later, the same group described an optimization of the test in order to increase the throughput and cost-effectiveness using a Multiplex model using different microbeads for the same T (telomeric region) and R (reference single gene) probes and then, pairs of probe sets are hybridized with DNA and grouped on a single plate for the other steps such as signal amplification, detection dye, wash and capture signal strength (Jasmine et al., 2018).

An alternative technique that has also been widely used is based on a kit designed to directly measure the TL of human cells such as Absolute Human Telomere Length Quantification qPCR Assay Kit (Cat# 8918) or Relative Human Telomere Length Quantification qPCR Assay Kit (Cat# 8908) (ScienCell Research Laboratories, Inc., Carlsbad, CA, United States). Basically, for each DNA sample, two consecutive reactions are performed: the first to amplify a single-copy reference (SCR) gene and the second for the telomere sequence. The SCR primer set recognizes and amplifies a 100 bp on human chromosome 17 and it is used as a reference for data normalization. Some recent studies have used this tool to measure the TL in research in different areas as, for examples, in hematologic disorders, environmental and occupational exposure and survival of people living with HIV (Babu et al., 2019; Moazzam et al., 2020; Shah et al., 2021).

Telomere measurements with digital real-time PCR

Luo et al. (2020) developed a method called START assay that consists of measuring telomeres from digital real time PCR (dPCR). The system used is the Fluidigm 48,770 digital array which contains 48 panels per 770 cameras (36,960 total), each compartment with a volume of 0.85 nL. The technique consists of digesting genomic DNA by the enzymes *HinfI* and *RsaI* ($1 \text{ U } \mu\text{L}^{-1}$), followed by diluting it by $7689 \text{ pg } \mu\text{L}^{-1}$ to efficiently partition single telomere molecules into individual compartments in the dPCR chip. The measurement of the telomere is made by comparing a standard curve, based on a synthetic telomere repetition sequence (CCCTAA)₁₅. From the concentration of synthetic DNA at 35 pM (320 kb), four serial dilutions are performed to achieve concentrations of 80 kb, 20 kb and 5 kb. For the absolute quantification of the TL, a standard curve of the average Ct value against log₁₀ (TL) is generated using the dilution series of 320 kb, 80 kb, 20 kb and 5 kb. The average length, the coefficient of variation and the percentage of short telomeres (<3 kb) for each sample are calculated based on the TL distribution obtained from the converted Ct values. The Ct of 27 was used as a cut-off value for detecting the TL, corresponding to ~0.2 kb. The technique was also designed to identify alternative telomere elongation mechanism (ATLs), based on the enumeration of ECTR molecules. ECTRs are DNA molecules containing telomeric repeat sequences that are not covalently linked to chromosomes. These molecules are described for participating in telomere cutting and maintenance events mediated by homologous recombination and have been observed to be present in ALT positive cancer cells (Cesare and Griffith, 2004; Chen et al., 2017).

The results of the study showed that the START assay showed a high and moderate correlation with the results of TRF ($R^2 = 0.96$) and qPCR ($R^2 = 0.78$), respectively; in addition to showing the presence of ATLs in cases where there was a greater number of telomere molecules per compartment in the START assay. The moderate correlation with qPCR is justified because the technique (qPCR) is dependent on the normalization of the single copy gene, which results in significant deviations due to aneuploidy, an event common to many types of cancer.

TL estimation from DNA methylation

Deviations in the length of telomeres are associated with several diseases related to aging. Therefore, they have been the subject of studies and, mainly, the length of the leukocyte telomeres (LTL), since their shortening is linked to cardiovascular diseases, psychological stress and life expectancy (Epel et al., 2004; Fitzpatrick et al., 2007; Needham et al., 2015). However, the methylation of cytosine residues from cytosine-guanine phosphate-dinucleotides (CpGs) is another marker that also changes with cell age (Horvath and Raj, 2018). Thus, from the methylation levels of the CpG bases, it is possible to generate specific algorithms capable of estimating the age of the DNA. Based on this context, Lu et al. (2019) developed a DNA methylation-based estimator of telomere length (DNAmTL) assay based on the methylation profile of 140 CpGs. For this, the study was divided into two groups for analysis, the first being composed by 3334 and the second by 9815 participants. Both had methylation levels measured by Illumina Infinium 450 k or EPIC 850 k arrays, and the first group also measured by telomere using the TRF technique. The authors estimated LTL based only on DNA methylation levels. The system was developed in an elastic network regression model implemented in the R glmnet package (Rizos et al., 2012).

The authors showed that using independent test data, DNAmTL exhibited moderately strong correlations with measurement of TL (based on Southern blotting or qPCR) in blood and adipose tissue of individuals from different racial groups. In short, DNAmTL outperformed LTL (based on Southern blotting or qPCR) in association with age ($r \sim -0.75$ for DNAmTL versus $r \sim 0.35$ for LTL), sex, ethnicity, lifestyle factors (diet, smoking, education, body mass index) and several clinical biomarkers (lipid and insulin levels). Furthermore, DNAmTL had a better predictive power than LTL for time to death ($P = 2.5E^{-20}$), coronary heart disease ($P = 6.6E^{-5}$) or heart failure ($P = 3.5E^{-6}$). It is important to note that the data focused only on blood samples, however, DNAmTL also applied to adipose and hepatic tissue, and to keratinocytes and fibroblasts (demonstrated in *in vitro* tests).

Genome-wide sequencing data to measure telomeres

The development of massive sequencing on a large scale has made it possible to analyze the sequences of telomeres on the scale of millions, as well as the entire genome. At first, the measurement of telomeres using sequencing data was not successful, because when comparing the already known measurement techniques, such as qPCR, the data obtained did not show results conformity (Aubert et al., 2012). Parker et al. (2012), as an example, showed that the use of TTAGGG or CCCTAA repetitions, as unit copies for data normalization, was inconsistent, since tumors constantly undergo aneuploidies (numerical chromosomal changes).

In Ding et al. (2014) developed the TelSeq program for estimating the TL based on genome-wide sequencing (GWS) data. For program validation, telomere measurement results from 260 leukocyte samples from United Kingdom twins (study called TwinsUK) (Moayyeri et al., 2013) and 96 samples from the 1000 Genomes Project (Durbin et al., 2010) were used. To verify the measurement's success by the program, the authors compared the results obtained from the measurement of telomeres by TRF with data from the total genome of the groups included in the study (Illumina 100 bp paired-end whole genome sequence). The basis for building the software was the analysis of the number of TTAGGG copies of the TwinsUK data, combined with the non-cyclic permutation of TTAGGG from the controls. This combination generated a multiplication equation for variables that estimate the TL. This equation consists of:

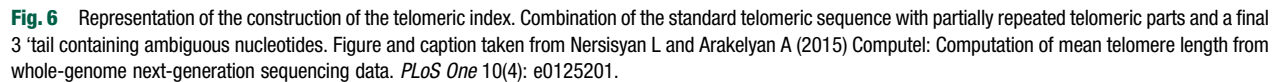

- (1) a constant telomeric reading abundance (based on the repetition readings threshold of the TTAGGG sequences);
- (2) a constant length of the genome divided by the number of ends of the telomere 46 (23×2);
- (3) the total number of readings per depth of the sequencing.

The results showed that TelSeq was able to present a high correlation with the data of the TRF technique ($\rho = 0.60$) ($P < 10E^{-16}$). Although TelSeq estimated a shortening higher than the TRF data (mean 5.63 kb compared to 6.97 kb, and shortening per year, 34.5 bp/year against 19.8 bp/year), the variation in the results was not significant ($P = .79$).

To access the software, it is available through the link: <https://github.com/zd1/telseq>.

Nersisyan and Arakelyan in 2015 developed an extension of the R program to calculate the average TL from GWS, called Computel. With characteristics similar to TelSeq, the system consists of an equation for measuring telomeres that takes into account:

- (1) Construction of a telomeric index based on: (a) a combination of the reading of telomeric repetition patterns (TTAGGGTT), (b) readings containing partially repeated telomeric parts (GGGTTAGGGT), and finally, (c) a 3'-final tail containing ambiguous nucleotides, in order to minimize the repetitions of reading of the telomeric region. This scheme can be seen in Fig. 6.
- (2) Mapping the readings to the telomeric index. Short readings of single or paired ends are aligned to the telomeric index with the bowtie2-align program;
- (3) Calculation of coverage in the telomeric index *;
- (4) Determination of the average coverage in the reference genome (optional) *;
- (5) Average TL estimate *.

The results generated by Computel showed a strong linear correlation (R^2) equal to 0.95 and 0.92 for single and paired end readings. Overall, Computel's performance showed a strong correlation with the average TL estimated with qPCR and TRF techniques, but it diverged to some extent (2–3 kb) in absolute values. In the case of TRF, this difference can be attributed to the capture of sub telomeric regions of the chromosomes, overestimating the length of the telomeres by 2.5–4 kb. On the other hand, Computel surpassed TelSeq in all cases analyzed. When the reading length ranges significantly changed (36, 76, 100, and 150 nucleotides), the telomere size was overestimated.

In 2018, the Telomerecat program (Farmery et al., 2018) was developed in order to measure telomeres with a high standard of veracity, correcting errors not considered by the TelSeq and Computel programs, such as aneuploidies (present mainly in cancer cells and non-human cells) and errors inherent to sequencing.

- (1) normalization is not done in relation to the whole genome, but in relation to sub telomeric regions;
- (2) the system corrects the number of readings originating from the so-called interstitial telomeric repetitions (ITRs). These erroneous regions of apparent telomeres and sub telomers may arise from other stretches of the TTAGGG repeat sequence that appear in the human genome (Riethman et al., 2004);
- (3) sequencing errors elimination. The sub telomer is composed of sub telomeric repetitions and segmental duplicates, interspersed with canonical repetitions. Thus, these repetitions are susceptible to variations, mutations and sequencing errors.

Telomerecat is available through the link <https://github.com/jhrf/telomerecat> and the installation guide at <https://telomerecat.readthedocs.io>.

Identification of the alternative telomere elongation mechanism by GWS

In addition to the t-type (TTAGGG) sequences, telomeres have repetition variations, such as type-c (TCAGGG), type-g (TGAGGG), and type-j (TTGGGG) (Varley et al., 2002; Lee et al., 2014) called telomeric variant repetitions (TVRs). The recombination between these repetitions forms the ATL. In 2019, the TelomereHunter program (Feuerbach et al., 2019) was developed to identify the presence of ATLs in WGS data.

The program consists of extracting at least six readings of non-consecutive repetitions of the TVR (t-, c-, g- or j-type). An equation considering the combination of readings and length of the sequenced fragment is generated. In the second moment, the readings extracted are categorized according to the alignment and quality of the mapping. That is, if the readings are aligned, the position of the strings is considered suitable for classification. The program considers all chromosomal bands, except the first and last band of a chromosome, as eligible for reading sequences considered to be intrachromosomal. The readings of these extremities, on the other hand, are categorized as intratelomeric. The telomere content is calculated as the fraction of intratelomeric readings per million readings. In addition, the system corrects the content of telomeres considering the content of GC between 48% and 52%. Finally, TVRs are quantified by looking for NNNGGG hexamers in intratelomeric readings. A particular focus is placed on singletons [(TTAGGG) 3-NNNGGG- (TTAGGG) 3], whose counts are normalized by the total number of readings in the sample.

The presence and absence of ATL in a medulloblastoma patient using TelomereHunter are represented by Figs. 8 and 9, from the original article by Feuerbach et al. (2019).

The software and installation documentation are available at <https://www.dkfz.de/en/applied-bioinformatics/telomerehunter/telomerehunter.html>.

Summary and perspectives

Since the discovery of the cellular maintenance mechanism involving telomeres, the evaluation of TL in several pathologies has been highlighted in many researches. Telomere shortening is inevitable under normal conditions, since with each cell division, the lagging-strand DNA is not fully synthesized. This mechanism tells the cell finally to stop cellular growth arrest and enter senescence or cell death, thus preventing tumor formation in humans and other long-lived animals (Shay, 2016; Maciejowski and de Lange, 2017). On the other hand, in tumors, telomere erosion is protected. In these cases, the cell activates telomerase, or promotes ATL. For this reason, telomere measurement techniques have gained interest and were developed. In this article, the main methodologies for measuring TL are summarized, from the introduction of the TRF in Moyzis et al. (1988), to the dPCR in Luo et al. (2020). It is clear that in future probably more new technologies will emerge in addition to therapeutic studies aimed at the telomere's molecular mechanism.

Glossary

Abortus This term is used to define a fetus or embryo removed or expelled from the uterus during the first half of gestation (20 weeks or less).

Buffy coat This is simply a concentration of all the white blood cells and platelets in a sample of blood. This can be obtained by centrifuging a sample of peripheral blood at 1200 rpm for 10 min.

Cell passaging This is also referred to as cell splitting. It is a technique that enables an individual to keep cells alive and growing under cultured conditions for an extended period of time. Cells should be passed when they are 90–100% confluent.

Fibroblast tissues This is the principal active cell of connective tissues. They are large, flat, elongated (spindle shaped) cells possessing processes extending out from the ends of the cell body. The cell nucleus is flat and oval.

Peripheral blood This is otherwise known as “whole blood”. It is a complete collection of various blood cells i.e., erythrocytes (red blood cells), leukocytes (white blood cells) and thrombocytes (platelets) suspended in blood plasma.

Stillborn An infant born dead. This is the death of a baby before or during delivery.

Trophoblast cells They are cells that form the outer layer of the “pre-formed” placenta. They are responsible for supply of nutrient to the developing embryo. These cells are formed during the first stage of pregnancy and they are among the first cells to undergo differentiation after fertilization of the egg.

Introduction

Gaps, cracks or lines indicating breakage(s) along the entire length or width of a chromosome strand are usually unnoticeable, and peradventure they become obvious, they are most often dismissed as being insignificant provided the chromosome set is complete. Unfortunately, a slight damage to a very important autosomal (somatic) or sex chromosome arm, for example, the long (q) arm of chromosome 13 at position 12.3, which happens to be the gene locus for BRCA2 genes (Chen and Parmigiani, 2007), or an alteration of the nucleotide sequence of a gene (coded for a specific character or function), or a mismatched sequence of genes on a chromosome or part of its strand, caused by hormonal imbalance, organ or system dysfunction, or influenced by external factors like chemicals, drugs, ultraviolet- or gamma radiation, or acquired by direct inheritance from either or both parents etc., can result in

mutation, depending on the magnitude of damage caused or level of alteration infused (Fargo et al., 2014). The effects of mutation can be partial or total, with minor or major alterations to specific family traits, character(s) or behaviourism. Diepoxybutane (DEB) is a very important chemical test that can aide visibility of cracks or gaps or breakages in autosomal chromosomes of specialized cells and tissues (Moghrabi et al., 2009). The term “Breakage analysis” is simply used to describe the procedure involved in the detection of these “gaps” or “cracks” domiciled on a complete chromosome strand.

Chromosome breakage analysis is a complex laboratory protocol used in the determination of genome instability or the degree of genetic variation of a particular individual from his or her lineage or ancestry. Chromosomal aberration can result in sicknesses like bone marrow dysfunction or failure, myelogenous leukemia, myelodysplastic syndrome, and an increased risk of contracting breast, ovarian, prostate and other forms of cancer (Chen and Parmigiani, 2007). Therefore, intending couples and families with known history of hormonal imbalance or inherited bone marrow failure syndromes (IBMFs) etc., are advised to undergo this test for their own benefit, in other to safeguard the lives of their children, wards and future progeny. Early detection of chromosomal aberration can be the difference between life and death, for a child with this abnormality. In essence, breakage analysis can be conducted on blood samples, fibroblast tissues and even trophoblast cells from developing embryo or fetus (Auerbach, 2015). In any case, the earlier the situation is diagnosed and reported, the better the chances of survival of the affected individual. The aim of this study is to provide a general laboratory protocol for breakage analysis and DEB testing. The protocols for each analysis was described below.

Methodology

Specimen specification and collection

For an individual with complete blood count (CBC) rated as normal or high, i.e., Red blood cells (RBC), white blood cells (WBC) and lymphocyte (L) count, about 5–10 mL of whole blood (Peripheral blood) should be collected in Sodium Heparin vacutainer tube or a pre-heparinized plastic syringe containing 0.2 mL sodium heparin. For individuals with low “CBC”, “WBC” or “L” count, breakage analysis can be conducted using fibroblast tissues from the skin or other part of the body. DEB and breakage analysis conducted on fibroblast tissues can equally reveal gaps, cracks or lines of breakages and radial formation on chromosome strands. This phenomenon is known as somatic mosaicism. Fibroblast breakage studies may also be preferable for patients in short supply of blood in their system (e.g., anemic patients), accident victims needing urgent blood transfusion, or patients with extreme phobia for needles or injection etc. In the case of pregnant women, a sample of the trophoblast cells, amniotic fluid or fetal blood can suffice for DEB testing and breakage analysis.

Diepoxybutane (DEB) test

The protocol for Diepoxybutane (DEB) treatment of biological samples (basically from humans) was extracted from the research of Auerbach (2015).

Peripheral blood

Laboratory requirements:

- Peripheral blood (5–10 mL).
- Complete RPMI 1640, 15% FBS medium and 1% (w/v) Phytohemagglutinin (PHA).
- PBS.
- Diepoxybutane (1,3-butadiene diepoxide), store at 4 °C.
- 1 µg/mL Colcemid (store at 4 °C).
- 0.075 M KCl (store at 37 °C).
- Fixative i.e., 3:1 (v/v) methanol/glacial acetic acid (freshly prepared).
- Syringe (10 mL capacity) equipped with 18½-G needle.
- 25 cm² tissue culture flasks.
- 15 mL sterile conical-bottom centrifuge tubes with caps.
- IEC clinical centrifuge or equivalent.
- Microscope slides (store in 70% ethanol).
- Inverted microscope.
- Additional reagents and equipment for collection of peripheral blood lymphocytes.

Procedure:

Freshly collected blood sample is required for this experiment. Aseptically transfer 18–25 drops of peripheral (whole) blood (about 0.4–0.5 mL), using sterile syringe with 18½-G needle, into a 25 mL-capacity tissue culture flask containing 10 mL complete RPMI 1640, 15% FBS and 1% PHA. Repeat the procedure eight times to produce replicates for the experiment. Incubate at 37 °C, with 5% CO₂ humidity, for 24 h. Prepare the required DEB treatment by adding 10 mL of PBS to test tube A, 6 mL to test tube B, and 4.5 mL to test tubes C and D, respectively. Furthermore, add 10 µL of DEB solution (fortified with 15% FBS) to test tube A, cap, and

mix gently. Transfer 4 mL from test tube A to B, cap, and homogenize the content by shaking manually, then aseptically transfer 0.5 mL (500 μ L) from test tube B to C, cap, and mix gently too. Complete the dilution process by pipetting 0.5 mL (500 μ L) from test tube C to D, homogenize the content manually and allow to stand for a few seconds. Prepare a blank treatment in test tube E (using sterile distilled water).

After incubation, pipette 25 μ L of the treatment solution from test tube C into three (3) out of the nine (9) incubated blood samples, label the flasks C1, C2 and C3, respectively. Repeat the procedure using test tube D and three (3) out of the six (6) remaining cultures and label the flasks D1, D2 and D3. Finally, pipette 25 μ L of the "blank treatment" from test tube E into the remaining cultures and label them as E1, E2 and E3, respectively. The final DEB concentrations in the flasks would be 0.10 μ g/mL (C1, C2 and C3), 0.01 μ g/mL (D1, D2 and D3) and 0.00 μ g/mL (E1, E2 and E3), respectively. Afterwards, incubate at 37 °C, under a controlled cloud of 5% CO₂, for 48–72 h. Add 2 mL of 1 μ g/mL Colcemid to each of the flask and incubate further for another 20 min. Transfer the content of each flask (both treated and untreated) to separate sterile conical-bottom centrifuge tubes (15 mL capacity each), cap, and centrifuge at 800–1000 rpm (in an IEC clinical centrifuge) for 10 min. Decant the supernatant, retaining about 0.5 mL of liquid, re-suspend the cell pellets at the bottom of the tubes in the leftover supernatant (0.5 mL) by flipping each tube manually (to aide homogenization). Add 5 mL of pre-warmed 0.075 M KCl and incubate for another 10 min at 37 °C, in a water bath.

Centrifuge again at 1000 rpm for 10 min. Completely remove the supernatant and gently add 1 mL of freshly prepared fixative without disturbing the cell pellets. Decant to remove fixative immediately (after 3–5 s) and repeat this procedure two more times. Afterwards, tap the tube gently to break up the pellets. Instantaneously, add fixative to re-suspend the cells without agglutination or cluster formation. Step up the volume to 8–10 mL with fixative. Break up any clumps by pipetting with a Pasteur pipet. Allow to stand for 30 min at 25 °C. At the end of 30 min, centrifuge at 1000 rpm for 10 min completely decant the supernatant and re-suspend the cell pellets in about 3–5 mL of fresh fixative. Allow to stand for another 10 min. Repeat this step once or twice, immediately or after a window period of 24 h. This procedure should be sufficient to remove red blood cell debris and further fix the remnant white blood cells. After successful removal of red blood cell debris from the culture, centrifuge at 1000 rpm for 10 min. Remove the supernatant, break the pellet, and add enough fixative (about 0.25–0.5 mL) to give the desired cell concentration for slide preparation. The procedure was adapted from [Auerbach \(2015\)](#).

Fibroblast tissues

In the absence of peripheral blood, DEB test can be performed on fibroblast cultures i.e., initiated from skin biopsies, excised pieces of lungs or skin fragments from an abortus or a stillborn etc.

Laboratory requirements:

- Fibroblast tissues.
- Complete DMEM medium (Supplemented with 20% FBS).
- PBS.
- Diepoxybutane (1,3-butadiene diepoxide), store at 4 °C.
- 1 μ g/mL Colcemid (store at 4 °C).
- Fixative i.e., 3:1 (v/v) methanol/glacial acetic acid (freshly prepared).
- 0.051 M (0.38% w/v) KCl.
- Tissue culture plates (60 mm capacity).
- Disposable scalpels.
- Punch (3 mm).
- Additional reagents and equipment for cell passaging and counting.

Procedure:

Collect fibroblast tissue with the aid of a 3 mm punch. Place the fibroblast tissue in 0.5 mL complete DMEM medium (fortified with 20% FBS) and cut to standard fragment (1 × 1 mm) using two sterile disposable scalpels, in a 60 mm tissue culture plate. Draw horizontal and vertical lines across the inner surface of three (3) sterile disposable tissue culture plates (60 mm capacity) using the pointed edge of a sterile scalpel. Transfer 5–6 excised pieces of fibroblast tissues into each of the 60 mm culture plate. Place the tissues at the intersect of the scored lines. The score lines will facilitate easy attachment of tissue fragments to the culture plates and also, tracing of tissue colonies. Incubate the scored plates, without any additional tissue culture medium, at 37 °C for 15–30 min, to allow the pieces of tissue to adhere to the plates. Afterwards, add 5 mL of complete DMEM medium (with 20% FBS) to each plate and incubate the cultures at 37 °C, with 5% CO₂. Replace the culture medium every 3–4 days without disturbing the tissue fragments. Use an inverted microscope to inspect the cultures for evidence of cell growth.

As soon as a huge patch of new fibroblasts cells surrounds the tissue fragments in the plate, carry out cell passaging and trypsinization by treating both the proliferated fibroblast cells and initial tissue fragments with 1 × trypsin/EDTA solution i.e., remove the medium in which the newly proliferated fibroblast cells were suspended by decanting the liquid without agitating the cell clusters, wash the monolayered-cell clusters with a reasonable quantity of saline solution, free of Ca²⁺ and Mg²⁺. Thereafter, remove the saline solution from the culture by decanting or with the aid of a Pasteur pipette. Add excess trypsin/EDTA solution to the culture such that the monolayers of cell clusters are completely submerged by the solution. Incubate the proliferated cell culture at 37 °C for 2 min in a mist of 5% CO₂. Afterwards, aseptically remove the trypsin/EDTA solution by decanting (without agitation)

and incubate the residual cells at 37 °C until cells start to detach from the surface of the monolayer cluster. The progress of cell detachment can be monitored intermittently by the use of an inverted microscope. Extreme care should be taken not to dislodge the cell colonies formed, as they will continue to proliferate in the culture, if undisturbed.

If there are more than enough fibroblast cells formed within any of the tissue culture flask, transfer some of the newly generated cells to a sterile tissue culture flask (25 mL capacity) submerged in complete DMEM/15% FBS solution (Note: reduce the concentration of FBS in the DMEM medium to 15% for this and all subsequent subcultures). These cells are designated as “first passage cells.” Add 1 × trypsin/EDTA solution when the first passage culture reaches convergence. Subculture at a 1:3 split ratio in complete DMEM/15% FBS. Cell passaging and trypsinization can be conducted until there are enough proliferated cells for the experiment. You can finally proceed with DEB treatment when at least three “second passage cultures” reach convergence. Plate the proliferated fibroblast cells in 5 mL complete DMEM medium (fortified with 15% FBS) in 25 mL capacity tissue culture flask (3×10^5 cells per flask). Incubate cultures at 37 °C, with 5% CO₂, for 24 h.

Prepare the required DEB treatment by adding 10 mL of PBS to test tube A, 6 mL to test tube B, and 4.5 mL to test tubes C and D, respectively. Furthermore, add 10 µL of DEB solution (fortified with 15% FBS) to test tube A, cap, and mix gently. Transfer 4 mL from test tube A to B, cap, and homogenize the content by shaking manually, then aseptically transfer 0.5 mL (500 µL) from test tube B to C, cap, and mix gently too. Complete the dilution process by pipetting 0.5 mL (500 µL) from test tube C to D, homogenize the content manually and allow to stand for a few seconds. Prepare a blank treatment in test tube E (using sterile distilled water).

After incubation, pipette 25 µL of the treatment solution from test tube C into three (3) out of the nine (9) incubated Fibroblast cells, label the tissue culture plates as C1, C2 and C3, respectively. Repeat the procedure using test tube D and three (3) out of the six (6) remaining cultures and label the tissue culture plates as D1, D2 and D3. Finally, pipette 25 µL of the “blank treatment” from test tube E into the remaining cultures and label the tissue culture plates as E1, E2 and E3, respectively. The final DEB concentrations in the treated tissue culture plates would be 0.10 µg/mL (C1, C2 and C3), 0.01 µg/mL (D1, D2 and D3) and 0.00 µg/mL (E1, E2 and E3), respectively. Afterwards, incubate all the tissue culture plates at 37 °C, under a controlled cloud of 5% CO₂, for 48–72 h. Add 2 mL of 1 µg/mL Colcemid to each of the treated tissue culture plates and incubate further for another 20 min. Transfer the content of each of the tissue culture plates (both treated and untreated) to separate sterile conical-bottom centrifuge tubes (15 mL capacity each), cap, and centrifuge at 800–1000 rpm (in an IEC clinical centrifuge) for 10 min. Decant the supernatant, retaining about 0.5 mL of liquid, re-suspend the cell pellets at the bottom of the tubes in the leftover supernatant (0.5 mL) by flipping each tube manually (to aide homogenization). Add 5 mL of pre-warmed 0.075 M KCl and incubate for another 10 min at 37 °C, in a water bath.

Centrifuge again at 1000 rpm for 10 min. Completely remove the supernatant and gently add 1 mL of freshly prepared fixative without disturbing the cell pellets. Decant to remove fixative immediately (after 3–5 s) and repeat this procedure two more times. Afterwards, tap the tube gently to break up the pellets. Instantaneously, add fixative to re-suspend the cells without agglutination or cluster formation. Step up the volume to 8–10 mL with fixative. Break up any clumps by pipetting with a Pasteur pipet. Allow to stand for 30 min at 25 °C. At the end of 30 min, centrifuge at 1000 rpm for 10 min. completely decant the supernatant and re-suspend the cell pellets in about 3–5 mL of fresh fixative. Allow to stand for another 10 min. Repeat this step once or twice, immediately or after a window period of 24 h.

Harvest cultures at the first mitotic stage (precisely, at the metaphase stage) after subculture (between 24 and 48 h). Add 1 mL of 1 µg/mL Colcemid (per 5 mL medium) to all the tissue culture plates, at 3 h prior to harvest. Incubate for another 3 h at 37 °C, with 5% CO₂. The timing for harvesting is determined by the intermittent inspection of the cultures with an inverted microscope. Metaphase cells appear rounded. Treat the fibroblast cells again with 1 × trypsin/EDTA solution (use the predefined trypsinization procedure). Transfer the contents of each tissue culture plates to a sterile 15 mL centrifuge tube, cap, and centrifuge for 10 min at 1000 rpm. Decant, retaining about 0.5 mL of liquid, re-suspend the cell pellets at the bottom of the tubes in the leftover supernatant (0.5 mL) by flipping each tube manually (to aide homogenization), with the careful addition of 5 mL of pre-warmed 0.075 M KCl. Incubate the mixture for 10 min at 37 °C, in a water bath. Afterwards, centrifuge at 1000 rpm for 10 min. Fix the fibroblast cells as described above for blood samples (Auerbach, 2015). Note: The hypotonic solution of KCl applied to the fibroblast cells should be more diluted than that used for peripheral blood cultures.

Trophoblast cells or Fetal blood

Trophoblast cells obtained by chorionic villus sampling (CVS) at 9–12 weeks of gestation, or amniotic fluid cells obtained by amniocentesis at 15–17 weeks of gestation, or even fetal blood can be analyzed for chromosome breakages.

Laboratory requirements:

- Fetal cells obtained by CVS or amniocentesis, enough to establish cultures in two (2) tissue culture flasks (25 mL capacity).
- PBS.
- Diepoxybutane (1,3-butadiene diepoxide), store at 4 °C.
- 1 µg/mL Colcemid (store at 4 °C).
- 0.075 M KCl (store at 37 °C).
- Fixative i.e., 3:1 (v/v) methanol/glacial acetic acid (freshly prepared).
- 25 cm² tissue culture flasks.
- 15 mL sterile conical-bottom centrifuge tubes with caps.
- IEC clinical centrifuge or equivalent.
- Microscope slides (store in 70% ethanol).

- Inverted microscope.
- Growth medium: 1:1 mixture of Chang medium and complete RPMI (fortified with 15% FBS).
- Additional materials and equipment for culture of chorionic villi and amniotic fluid.

Procedure:

Establish fetal blood or trophoblast cells or amniotic fluid cultures in the preferred growth medium within 25 mL capacity tissue flasks and incubate at 37 °C, with 5% CO₂. Treat the cultured fetal cells with 1 × trypsin/EDTA solution and subculture when there are noticeable clusters of massive active proliferating cells present in each culture flask. Do not allow colonies to become overgrown. Use a split ratio of 1:2 or 1:3 to subculture proliferated fetal cells i.e., If there are more than enough proliferated fetal blood- or trophoblast- or amniotic fluid cells formed within any of the tissue culture flask, transfer some of the newly generated cells to a sterile tissue culture flask (25 mL capacity) submerged in complete DMEM/15% FBS solution (Note: reduce the concentration of FBS in the DMEM medium to 15% for this and all subsequent subcultures). These cells are designated as “first passage cells.” Add 1 × trypsin/EDTA solution when the first passage culture reaches convergence. Subculture at a 1:3 split ratio in complete DMEM/15% FBS. Cell passaging and trypsinization can be conducted until there are enough proliferated cells for the experiment. You can finally proceed with DEB treatment when at least three “second passage cultures” reach convergence. Plate the proliferated fetal blood- or trophoblast- or amniotic fluid cells in 5 mL complete DMEM medium (fortified with 15% FBS) in 25 mL capacity tissue culture flask (3 × 10⁵ cells per flask). Incubate cultures at 37 °C, with 5% CO₂, for 24 h.

Prepare the required DEB treatment by adding 10 mL of PBS to test tube A, 6 mL to test tube B, and 4.5 mL to test tubes C and D, respectively. Furthermore, add 10 µL of DEB solution (fortified with 15% FBS) to test tube A, cap, and mix gently. Transfer 4 mL from test tube A to B, cap, and homogenize the content by shaking manually, then aseptically transfer 0.5 mL (500 µL) from test tube B to C, cap, and mix gently too. Complete the dilution process by pipetting 0.5 mL (500 µL) from test tube C to D, homogenize the content manually and allow to stand for a few seconds. Prepare a blank treatment in test tube E (using sterile distilled water).

After incubation, pipette 25 µL of the treatment solution from test tube C into three (3) out of the nine (9) incubated fetal blood or trophoblast cells or amniotic fluid samples, label the flasks C1, C2 and C3, respectively. Repeat the procedure using test tube D and three (3) out of the six (6) remaining cultures and label the flasks D1, D2 and D3. Finally, pipette 25 µL of the “blank treatment” from test tube E into the remaining cultures and label them as E1, E2 and E3, respectively. The final DEB concentrations in the flasks would be 0.10 µg/mL (C1, C2 and C3), 0.01 µg/mL (D1, D2 and D3) and 0.00 µg/mL (E1, E2 and E3), respectively. Afterwards, incubate at 37 °C, under a controlled cloud of 5% CO₂, for 48–72 h. Add 2 mL of 1 µg/mL Colcemid to each of the flask and incubate further for another 20 min. Transfer the content of each flask (both treated and untreated) to separate sterile conical-bottom centrifuge tubes (15 mL capacity each), cap, and centrifuge at 800–1000 rpm (in an IEC clinical centrifuge) for 10 min. Decant the supernatant, retaining about 0.5 mL of liquid, re-suspend the cell pellets at the bottom of the tubes in the leftover supernatant (0.5 mL) by flipping each tube manually (to aide homogenization). Add 5 mL of pre-warmed 0.075 M KCl and incubate for another 10 min at 37 °C, in a water bath.

Centrifuge again at 1000 rpm for 10 min. Completely remove the supernatant and gently add 1 mL of freshly prepared fixative without disturbing the cell pellets. Decant to remove fixative immediately (after 3–5 s) and repeat this procedure two more times. Afterwards, tap the tube gently to break up the pellets. Instantaneously, add fixative to re-suspend the cells without agglutination or cluster formation. Step up the volume to 8–10 mL with fixative. Break up any clumps by pipetting with a Pasteur pipet. Allow to stand for 30 min at 25 °C. At the end of 30 min, centrifuge at 1000 rpm for 10 min. completely decant the supernatant and re-suspend the cell pellets in about 3–5 mL of fresh fixative. Allow to stand for another 10 min. Repeat this step once or twice, immediately or after a window period of 24 h.

Harvest cultures at the first mitotic stage after subculture (between 24 h and 48 h). Add 1 mL of 1 µg/mL Colcemid (per 5 mL medium) to all the flasks, at 3 h prior to harvest. Incubate for another 3 h at 37 °C, with 5% CO₂. The timing for harvesting is determined by the intermittent inspection of the cultures with an inverted microscope. Metaphase cells appear rounded. Treat the fetal blood- or trophoblast- or amniotic fluid cells again with 1 × trypsin/EDTA solution (use the predefined trypsinization procedure). Transfer the contents of each flask to a sterile 15 mL centrifuge tube, cap, and centrifuge for 10 min at 1000 rpm. Decant, retaining about 0.5 mL of liquid, re-suspend the cell pellets at the bottom of the tubes in the leftover supernatant (0.5 mL) by flipping each tube manually (to aide homogenization), with the careful addition of 5 mL of pre-warmed 0.075 M KCl. Incubate the mixture for 10 min at 37 °C, in a water bath. Afterwards, centrifuge at 1000 rpm for 10 min. Remove the supernatant, break the pellet, and add enough fixative (about 0.25–0.5 mL) to give the desired cell concentration for slide preparation. The procedure was adopted from Auerbach (2015).

Breakage analysis

Staining of chromosomes

The Giemsa staining technique is the procedure adopted for chromosome staining in this research. Giemsa stain is a histological stain with a particular affinity for nuclei and chromosomes. The procedure is simple and results in the formation of cluster-free reddish-blue to purple nuclei or chromosomes.

Laboratory Requirements:

- Gurr's buffer tablets (pH 6.8).
- Giemsa stain.

- Metaphase chromosome slides.
- Permount histological mounting medium.
- Coplin jars.
- Sterile distilled water (dH₂O).

Procedure:

Dissolve one (1) Gurr's buffer tablet in 1Ltr of sterile distilled water. Setup five (5) Coplin jars i.e., one (1) for the Giemsa stain, one (1) for the Gurr's buffer and three (3) successive jars for sterile distilled water. Add 4 mL of Giemsa stain to 46 mL of the freshly prepared Gurr's buffer in the staining jar.

Note:

1. Lifespan of the stain is 1 h, therefore, staining solution must be prepared fresh before each use.
2. Chromosomes used for this experiment should be at the metaphase stage.

Fix a tiny portion of the harvested chromosomes on a clean slide. Gently streak the chromosomes on the slide to allow even distribution of the chromosome arms. Flood the fixed chromosomes on the slide with freshly prepared Giemsa stain for 5 min, rinse by dipping several times into the Coplin jar containing Gurr's buffer, afterwards, rinse the slide by dipping several times in succession of sterile distilled water. Air dry the slide in a Laminar air flow chamber. Afterwards, check each slide for stain intensity. Stain intensity should be sufficient so that gaps and breaks in the chromosomes appear as achromatic (non-stained) regions. Select slides that are well stained and insert coverslips on them using Permount histological mounting medium (Auerbach, 2015). A total of between 50 and 100 slides should be prepared for observation and scoring.

Chromosome analysis for breakages and aberration using an inverted microscope

Procedure:

The protocol adapted in the description of breakage analysis was an extract from the research of Fargo et al. (2014). The procedure is described thus: Add few drops of cell suspension on each microscope slides. Stain with Giemsa or Wright stain and observe under an inverted microscope. Fifty (50) cells from each Clastogen should be scored for chromosome breaks and radial formations using a Nikon Eclipse E800 Photoscope. Representative images should be captured using either CytoVision (Applied Imaging) or Applied Spectral Imaging software. Aberrations should be recorded as the number of cells with specific numbers of breaks or radials, as well as the number of breaks in radial-containing cells. While the actual structure of radial figures remains unknown, each radial figure should be assigned a value of two breaks for the purpose of incorporating these data into the overall averages. Test Statistics that may be useful in quantifying chromosome breakages include total breaks per cell, percentage of aberrant cells, and breaks per aberrant cell, as well as the chromosome fragility index (CFI), which is breaks per aberrant cell multiplied by the percentage of aberrant cells as stated by Castella et al. (2011). Other test statistics useful in the determination of the level of chromosome breakages or aberration not referenced in this article, can be used in other to obtain optimal results and better diagnosis of each case treated.

Theoretic standards for scoring breakages

The mean baseline chromosomal breakage frequency in peripheral blood lymphocytes ranges from 0.00 to 0.05 breaks per cell in normal control or negative test results, and 0.00 to 0.12 for equivocal and positive test results. The mean DEB-induced chromosomal breakage frequency in peripheral blood lymphocytes for normal control individuals ranges from 0.00 to 0.10 breaks per cell, and 0.00 to 23.9 breaks per cell for equivocal and positive test results. It is important to note that in cultures from samples with breakages, the percent of metaphases exhibiting the high number of chromosomal breaks and exchanges can vary from as low as 10% to as high as 100%. A multivariate regression analysis of data from DEB studies shows that discrimination between DEB⁺ and DEB⁻ patients is best achieved by calculating breakage as breaks per cell (Auerbach et al., 1989). Also, presence of radial configurations (at two concentrations of DEB, in a strong dosage-dependent manner) is an important factor in confirming a positive result (Auerbach, 2015).

Scoring of chromosomal aberrations and breakages

Carry out a systematic selection on the already fixed metaphases to be analyzed by viewing under an inverted microscope at ×400 magnification. To save time, select only metaphase slides adjudged to be suitable, in terms of chromosomal integrity, for evaluation. To avoid a bias for relatively undamaged metaphases, do not at this stage select on the basis of "quality," since "nice-" looking metaphases tend to have fewer aberrations. Rather, every next metaphase encountered should, in principle, be scored, unless it must be rejected because it fails to meet the observer's criteria for adequate spreading, state of condensation of the chromosomes (not too long or too short), adequate staining and morphology (clearly recognizable chromosomes with clearly visible centromeres), and adequate ploidy (Auerbach, 2015). When a metaphase slide meets these criteria, that metaphase must be observed and scored using a magnification of x1,000 under an inverted microscope, even if "difficult" aberrations are subsequently encountered (Auerbach, 2015), therefore, a direct comparison is made using normal chromosomes (Fig. 1) from the control experiments. However, be sure to score only actual aberrations. Also, care should be taken such that the aberrations noted on the chromosomes were not artificially inflicted by the analysts, either by commission or omission, as a wrong analysis might signal a wrong medical action by health experts or clinicians (doctors and other health care officers).

Fig. 1 A complete chromosome structure showing all the essential parts.

Fig. 2 Chromosome structure showing chromatid gap.

Fig. 3 Chromosome structure showing chromatid break and the dislodged part.

Itemized below are some very helpful tips for decision making while scoring chromosome breakages and aberrations:

1. Chromatid gap: This is usually perceived by laboratory technicians as an interruption in the staining of a chromatid 1–2 times the width of that chromatid (Fig. 2). Chromatid gaps result from breakage or damage to the chromosome arm. The affected part on the chromatids appears transparent when observed under an inverted microscope after staining.
2. Chromatid break: This is a situation where the interruption in the staining of the chromatid is more than two times the width of that chromatid, or a situation where the broken piece of chromatid appears dislocated or dislodged (Fig. 3). Chromosomes with chromatid break appear to be shorter in the affected chromatid or chromosome arm than the other arm. The fragmented piece can be spotted close to the affected chromosome in most cases.
3. Triradial chromosome: This is an interchange figure presumably having resulted from the disrepair of two breaks in two distinct chromosomes (Fig. 4). Triradial structures are mostly formed when the dislodged arm is attached to the wrong chromatid, creating a kind of skewed appearance of the chromosome. Now, in a bid to repair itself, the affected chromosome tends to form a linkage with the chromatid of a different chromosome too, producing a sort of unbalanced physical appearance.
4. Quadriradial chromosome: This is also an interchange figure resulting from the disrepair of two broken chromatids in different chromosomes (Fig. 5). Quadriradial structures appear as a mismatched chromosome linkage. In this case, there is a union

Fig. 4 Chromosome structure showing triradial formation.

Fig. 5 Chromosome structure showing quadriradial formation.

Fig. 6 General chromosome aberrations.

between the arms of two (2) chromosomes forming a tetrad of chromatid structures. The chromatid arms may or may not appear broken or disjointed. The linkage most times occur between sister chromosomes but in rare cases, linkages may be formed between adjacent chromosome pairs. The reason behind the mismatched linkages can be probed by researchers in order to shed more light to the current study.

5. Other chromatid interchange and Chromosome-type changes, such as dicentrics, acentric fragments (Fig. 6), and ring chromosomes, may be recorded, but these aberrations, which are extremely rare with the protocol used, should not be included in the final analysis (Auerbach, 2015). There are variants of chromosomal aberrations not listed in this article. Therefore, before carrying out DEB testing and breakage analysis on any biological sample, the medical personnel should be sure to acquaint himself or herself with the numerous chromosome structures that abound, so that a false-positive or false-negative diagnosis can or may be avoided.

Complementation (mutation) analysis

The complementary molecular test for breakage analysis described in this test was an excerpt from the research of Moghrabi et al. (2009). Extraction of DNA, RNA and cDNA from fibroblast tissues should be carried out after culturing the fibroblast tissues. The fibroblast tissues collected should be cultured using the standard technique described in section "Diepoxybutane (DEB) test" (Auerbach, 2015), thereafter, gDNA extraction can be conducted using the modified version of organic extraction protocol described by Pulsipher et al. (1998). Extraction of gDNA from each cell line should be initiated as soon as the number of proliferated fibroblast cells increase in the culture medium. At first, cell passaging and trypsinization should be conducted on the newly proliferated monolayered cell clusters. Trypsinization is a simple laboratory protocol used to separate cells formed in clusters, the steps involved in trypsinization include removal of the medium in which the newly proliferated fibroblast cells were suspended by decanting the liquid without disturbing the cell clusters, then wash the monolayered-cell clusters with enough saline solution, free of Ca^{2+} and Mg^{2+} , in order to remove traces of blood serum. Thereafter, remove the saline solution from the culture by decanting or with the aid of a Pasteur pipette. Add excess trypsin/EDTA solution to the culture such that the monolayers of cell clusters are completely submerged by the solution. Incubate the proliferated cell culture at 37 °C for 2 min in a mist of 5% CO_2 . Afterwards, aseptically remove the trypsin/EDTA solution by decanting (without agitation) and incubate the residual cells at 37 °C until cells start to detach from the surface of the monolayer cluster. The progress of cell detachment can be monitored intermittently by the use of an inverted microscope. The time required for total cell detachment from the monolayer cell cluster depends on the cell type, population density of the clusters, serum concentration in the growth medium, and the quality of the trypsin/EDTA solution applied.

After trypsinization, the detached cells (7×10^5 to 2×10^6) were washed in $1 \times$ phosphate-buffered saline and cell pellets were resuspended in 465 μL Nuclei Dropping buffer (0.075 M NaCl, 0.024 M EDTA). Ten-microliter proteinase K (10 mg/mL) and 25 μL 10% SDS were added to the suspension mix and was incubated at 37 °C for 16 h. This was followed by organic extraction using standard protocol (Ausubel et al., 1992; Moghrabi et al., 2009). Total RNA, enriched for mRNA, can be extracted from each of the cell lines using the RNeasy Mini Kit (Qiagen, Valencia, CA). A QIA-shredder (Qiagen) can be used to homogenize the lysate and a RNase-Free DNase Set (Qiagen) can also be used on-column to digest DNA during the RNA purification (Moghrabi et al., 2009). The resulting RNA should be reverse-transcribed, using RT-PCR, to cDNA. The procedure involved is stated thus: 10 μL of RNA should be denatured at 65 °C for 10 min and then added to 10 μL of $1 \times$ RT Buffer (Invitrogen, Carlsbad, CA), 10 mM dithiothreitol, 50 μM Roche Pd(N)₆ random primers (Roche, Nutley, NJ), 0.2 mM dinucleotide triphosphates (dNTPs), 10 U/ μL SuperScript II Polymerase (Invitrogen), and 2 U/ μL Roche Protector RNase Inhibitor (Roche). Amplification should be performed in a PTC-200 Peltier Thermal Cycler (MJ Research, Waltham, MA) as follows: 25 °C for 10 min, 42 °C for 50 min, 70 °C for 15 min, and thereafter, stored at 4 °C (Moghrabi et al., 2009).

Primers used for this experiment should be obtained from the NCBI GenBank database (See Moghrabi et al. (2009) for Primer selection and design of cDNA). Also, controls (Positive and Negative gDNA samples) should be obtained from the appropriate sources, for test validation, accuracy of clinical diagnosis and/or specificity of the breakage analysis conducted (Adachi et al., 2002; Ameziane et al., 2008; Callén et al., 2005; Chandra et al., 2005; Morgan et al., 2005; Yagasaki et al., 2004). A summary of the procedure is described thus: A total of 50 μL volume containing 150 ng of gDNA, 15 pmol of each primer, and 10 mM dNTP should be setup for PCR amplification of gDNA (Note: Additional reagents can be added to meet up with the specificity of the desired primers). Initiate an initial denaturation at 95 °C for 4 min, followed by amplification of 33 cycles, each with denaturation at 95 °C for 35 s, annealing at 64 °C for 40 s with a decrease of 0.1 °C/cycle, and extension at 72 °C for 40 s. The final extension should be carried out at 72 °C for 5 min. Primers should be stored at 4 °C. Specific primers can be designed using "OligoAnalyzer 3.0" software (Integrated DNA Technologies, Coralville, IA). Note: All primer sequences should be tailed by M13 forward and reverse primers to allow for efficient sequencing. In the case of apparent homozygosity in samples collected, alternate primers should be designed to rule out allele dropout.

The PCR amplification of cDNA should be performed thereafter as follows: add 5 μL of the resulting RT-PCR reaction (described above) to $1 \times$ HiFi Buffer (Invitrogen), 2 mM MgSO_4 , 0.8 mM dNTPs, 0.6 μM forward and reverse primers, 0.04 U/ μL Platinum HiFi Taq Polymerase (Invitrogen), and water to make a total volume of 50 μL . Amplification cycling conditions is as described for gDNA above (The conditions can be modified to suit the primers selected). The PCR products should be analyzed to determine their quality by running 5 μL of the amplified product on 2% NuSieve (Lonza, Rockland, ME) agarose gel in standard tris-acetate buffer at 8mAmp/cm gel (Moghrabi et al., 2009). Also, the PCR products should be analyzed for sequence variants by the detection of heteroduplex DNA using dHPLC on the WAVE HT system (Transgenomics, Omaha, NE) by means of acetonitrile gradient and Navigator software (Transgenomics). The procedure is described for both heterozygous and homozygous mutants. For heterozygous mutations, denature 10–15 μL of the amplified PCR products for 5 min. Cool gradually to a temperature of 25 °C, at a rate of 1 °C/min, to allow the optimum formation of heteroduplexes. For homozygous mutations, mix equal amount of DNA sample from the cultured fibroblast cells and a negative control, denatured, and analyzed on dHPLC as described above. Amplicons should be scored as dHPLC positive if a peak shift was detected on dHPLC relative to the appropriate controls (Positive and Negative).

Positive dHPLC amplicons should be analyzed further by sequencing. M13 forward and reverse primers should be used for this reaction. Purify the amplicons using ExoSAP-IT treatment (USB, Cleveland, OH) by incubating 5 μL with 2 μL ExoSAP-IT at 37 °C for 15 min, followed by heat inactivation at 80 °C for 15 min. Half of the volume of the inactivated amplicons should be aliquoted to a fresh tube, followed by the addition of M13 forward or reverse primer to a final concentration of 0.16 μM . The BigDye Terminator v1.1 Cycle Sequencing Ready Reaction-mix kit (Applied Biosystems, Foster City, CA) is recommended for this reaction.

Add 1 μL of the BigDye Terminator and 1.5 μL of $5\times$ BigDye buffer in a final sequencing reaction volume of 10 μL . Initiate sequencing 96 °C for 1 min, 25 cycles at 96 °C for 10s, 50 °C for 5 s, and 60 °C for 4 min. The sequenced amplicons should be purified using DyeEx 96 gel filtration plate (Qiagen, Valencia, CA) in line with the manufacturer's instructions. The purified amplicons should be transferred to an Optical 96-well plate (Applied Biosystems) and dried in a 70 °C heat block with forced ventilation for 15 min. The sequenced should be resuspended after drying in 15 μL Hi-Di formamide (Applied Biosystems) and separated on ABI PRISM 3100 Genetic Analyzer using a 50 cm capillary array and POP6 polymer (Applied Biosystems). DNA trace sequences can be generated from raw sequence data using Sequencing Analysis v5.1.1 (Applied Biosystems) and analyzed for sequence information using Mutation Surveyor software, version 3.01 (Soft Genetics, State College, PA). Novel variants detected should be analyzed in silico as described by Moghrabi et al. (2009).

Finally, Multiplex ligation-dependent probe amplification (MLPA) analysis should be performed on the samples and controls. The protocol for MLPA using SALSA P031/P032 (MRC-Holland, Amsterdam, Netherlands) is described thus: Denature 200 ng of gDNA and hybridize with each of SALSA P031 and P032 probes following the manufacturer's instructions. Perform ligation and PCR amplification according to manufacturer's instructions too. One microliter of the probe amplified product should be mixed with 0.3 μL GeneScan-500 ROX size standard (Applied Biosystems), 9 μL Hi-Di formamide (Applied Biosystems) and resolved using the ABI 3100 Avant Genetic Analyzer with a 36 cm capillary array and POP4 polymer (Applied Biosystems). GeneMapper v.3.5 software (Applied Biosystems) can be used for fragment analysis and the resulting peak height and size area can be exported thereafter as Microsoft Excel files. Subsequent quantitative and statistical analysis can be performed on the data generated. The most essential calculations include the peak heights (and areas) of the expected MLPA products (divide each peak height (and area) by the combined height (and area) of all peaks in the sample). For the three normal controls, the mean ($n = 3$) of the normalized peak heights (and areas) can be calculated from all the probes for each probe-mix P031 and P032. For the patients' samples and the positive control, each of the normalized peak height (and area) should be divided by the corresponding mean of the normalized peak height (and area) of the normal controls ($n = 3$). The resulting values should be compared with that of the standard normal control. All exons or amplicons differing by more than 30% from the normalized peak heights (and areas) of the standard normal control with similar fragment size should be considered as altered. The observation of reduced values indicates possible gene deletion, whereas increased values indicates potential gene duplication (Moghrabi et al., 2009).

Result interpretation for breakage analysis

Positive Test Result: A sample is confirmed as having cracks or gaps in the autosomal chromosomes if the lymphocytes show a substantial increase in chromosomal breakage and rearrangement after treatment with DEB. Characteristically, more than 90% of the lymphocytes in the sample will show increased breakage, and the rates and types of breakage observed will fall within the abnormal range. In the event of a positive test result, follow-up tests should be performed to identify the type of genetic mutation(s) induced by the chromosome breakage (gene deletion or insertion) using the molecular methods described by Moghrabi et al. (2009) in Section "Complementation (mutation) analysis".

Negative Test Result: A test result is considered to be negative if the patient's lymphocytes do not show increased chromosomal breakage or rearrangement in response to DEB, and the types and rates of breakage are within the normal range. If the chromosome breakage test is negative, no further studies are needed.

Equivocal Test Result: Test results are considered equivocal, or inconclusive, if the percentage of cells that display chromosomal breakage patterns are much lower than the normal control (but there is strong clinical evidence that the patient may have other underlying or related genetic illnesses) or if there is increased breakage but the individual shows no clinical symptoms of genetic diseases. For Equivocal results, DEB test and breakage analysis on skin fibroblast should be performed to rule out the possibility of mosaicism.

Note: Mosaicism is characterized by two distinct populations of lymphocytes in the blood. One population has normal sensitivity to DNA cross-linking agents due to a spontaneous correction of mutation, while the other population is hypersensitive to DNA cross-linking agents due to the presence of uncorrected mutants.

Conclusion

DEB testing and breakage analysis are very important laboratory protocols useful in the determination of gaps, cracks or breakages along the entire length of a chromosome. The detection of cracks, gaps or breakages on a particular chromosome is an indication that useful genetic materials are lost from that chromosome either by commission or omission. The amount of genetic materials lost by a single chromosome depends on the degree of breakages, gaps or cracks found on the chromosome. The medical implication of chromosome breakage is that there is a 50% chance of possible insertion or deletion of genes from that particular chromosome, which may play important role(s) such as physical development of an individual, reproduction, blood formation (in the case of anemic patients), normal functioning of the heart, lungs, kidneys, or brain etc. Therefore, couples are advised to add this test to the list of tests they have to undergo before getting married, as this might be a crucial decisive factor in the general well-being of their children, future progeny or even lineage. Parents or families with known history of inherited bone marrow failure syndrome (IBMFS) or other forms of aplastic syndromes (AS), should carry out the test for all their family members and relations, as early diagnosis can prove to be life-saving for an individual with chromosomal aberrations.

Invasive bacterial infection

Invasive bacterial infections (IBI) are leading causes of global morbidity and mortality among all age groups, especially young children and elders (Scelfo et al., 2021). Invasive bacteria are pathogens that can invade parts of the body where microorganisms are not normally present, such as the bloodstream, soft tissues like muscle or fat and the meninges, and are often associated with diseases, such as meningitis (inflammation of the tissues that cover the brain and spinal cord), pneumoniae, endocarditis and septicemia (or sepsis) (Archibald and Quisling, 2013; Holland et al., 2016; Reinhart et al., 2017; Weiser et al., 2018). Often, the infection has a bacterial origin, but it can also be caused by fungi, viruses or parasites (Dolin et al., 2019). The most common bacterial agents of these life-threatening diseases are *Neisseria meningitidis*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Streptococcus agalactiae*, *Escherichia coli*, *Klebsiella* spp., and *Pseudomonas aeruginosa*, which normally are found in the nasopharynx, throat or the gut and genitourinary tract of healthy individuals and are transmitted via respiratory route or, in the case of newborns, during the partum (Weiser et al., 2018; Raabe and Shane, 2019; Brueggemann et al., 2021; Deghmane and Taha, 2021).

Recently, the World Health Organization (WHO) estimated that 30 million cases and 6 million deaths come from bacterial-associated infection and affect people around the globe each year (Reinhart et al., 2017; Candel et al., 2018). Septicemia is one of the principal causes of mortality in critically ill patients. Approximately 70% of septicemia cases are community-acquired and the evaluation of patients with symptoms can be challenging and requires a combination of clinical observation and laboratory support (Gül et al., 2017). The survival of the patients depends on the rapid and accurate diagnosis of the infection and the appropriate treatment to prevent unnecessary deaths and upcoming incapacities (Gotts and Matthay, 2016). Although the elderly, immunosuppressed and children are known to be high-risk groups, IBI can affect any individual (Nasa et al., 2012; Holland et al., 2014; Zea-Vera and Ochoa, 2015; Emr et al., 2018; Szabo et al., 2019). Though, the higher mortality rate is associated to hospitalization and these populations often have concurrent medical or surgical conditions that delay the diagnosis and treatment, particularly when infections are associated with nosocomial infections and progress to shock and organ failure (Schorr et al., 2016). Many patients will have a long recovery, organs and tissues infected may be permanently damaged or painful, and organ dysfunction can occur (Gül et al., 2017).

The “gold standard” method for the patient diagnosis is based on laboratory techniques that rely on *in vitro* blood culture in enriched medium, followed by identification and susceptibility testing of the pathogen using standard biochemical techniques and integrating morphologic, metabolic, and physiologic analysis with differential staining methods (Mancini et al., 2015; Guido Marcello et al., 2016; Rizal et al., 2020). Microscopy, although rapid, is insensitive, requiring a relatively large concentration of bacteria ($\geq 10^5$ CFU mL⁻¹) to become positive and it is not part of routine diagnostics (Wiwanitkit et al., 2005). On the other hand, blood cultures can detect a wide range of microorganisms and are well established in the diagnostic pathway, achieving a sensitivity of >95% if sample volumes are sufficient. Adequate sampling volume is the most important factor for detecting a microorganism, since 50% of patients have a low bacterial amount circulating in blood (<1.0 CFU mL⁻¹). The recommendation is four bottles (with a capacity of 10 mL each one) of blood to be cultured for an initial evaluation in order to reach about 90–95% detection rate in a patient with documented infection (Townes et al., 2010; Dubourg and Raoult, 2016). Blood cultures are currently performed with fully automated instruments that detect microbial growth by the analysis of CO₂ release using fluorescent or colorimetric sensors; or, alternatively, pressure changes in the bottle headspace due to the consumption and production of gasses (Mancini et al., 2010), which does not allow pathogen identification.

However, despite these advances, this method has its limitations and is not the ideal approach for guiding initial therapy, since blood cultures requires several days before the results are available and can delay the introduction of an adequate antimicrobial therapy (Mancini et al., 2015; Guido Marcello et al., 2016; Sweeney et al., 2019). Typically, the growth of pathogens in medium

Fig. 1 Conventional workflow to detect bacterial infection. After examination of the patient, the physician may decide to take a blood or tissue sample. Subsequently, the sample has to be transported to the laboratory where it will be incubated. After incubation, standard approaches may allow the microorganism identification in 7 days, whereas molecular approaches permit identification within 48 h.

broth takes 24–72 h and requires Gram staining followed by additional overnight growth to yield single colonies for identification and susceptibility testing (Liesenfeld et al., 2014). Negative results can only be reported after 5–7 days. Nevertheless, culture-based diagnosis is not convenient for infections if the antibiotic treatment is initiated before blood sampling, in presence of a very low number of circulating bacteria, or when the microorganism is fastidious or uncultivable (Mancini et al., 2015). However, once the bacterium is isolated and the antibiogram performed, the microbiological report permits a reduction in the spectrum of empirical administered anti-infectious drugs, allowing the administration of the adequate antimicrobial treatment. Fig. 1 provides an overview and a comparison of the diagnostic and identification process of a bacterial infection using standard methods and molecular techniques.

In the past few years, molecular techniques have evolved as an alternative for the diagnosis of an IBI. Molecular diagnostics are based on the detection of bacterial DNA in the blood using polymerase chain reactions (PCR) and have been developed for direct testing of whole blood, without the need of culture (Marco, 2017). Although rapid, these assays have some limitations. PCR is a very powerful method to detect bacterial DNA in blood, even at low yield, but a single PCR it is not able to differentiate between different bacterial species, and require different tests for every species (Barghouthi, 2011). Several studies have also highlighted the requirement of strategies for differentiating between true infections and contaminations and, even though this method gives results in a short period, it has not yet reached clinical practice (Yang and Rothman, 2004).

The use of infection-associated biomarkers has been recommended to compensate the limitations of molecular diagnostic assays. To identify suitable samples, clinical criteria should be complemented by the use of inflammatory biomarkers, such as the total white cell count, neutrophil count, C-reactive protein (CRP), procalcitonin (PCT) and CD64 expression on neutrophils to predict severe systemic bacterial infection (Icardi et al., 2009; Cid et al., 2010; Rogina et al., 2014; Enguix-Armada et al., 2016). Procalcitonin is the best validated biomarker that discriminates the non-infectious cause for invasive bacterial infection (Enguix-Armada et al., 2016; Jekarl et al., 2019; Hamade and Huang, 2020). Presepsin, kallistatin, testican-1 and pro-adrenomedullin are new biomarkers useful for early diagnosis and prognosis in septic patients (Mierzchała-Pasierb and Lipińska-Gediga, 2019; Ito and Ishida, 2020). However, these biomarkers lack the specificity to discriminate between patients with an acute inflammatory response to trauma or surgery and those with a new infection (Ito and Ishida, 2020). Fig. 2 summarizes the most used methods to identify microorganisms from positive blood cultures or whole blood. In this chapter we will address only diagnostic approaches that involve 16S rRNA genomics, namely conventional and real-time PCR, hybridization, and next generation sequencing.

Fig. 2 Molecular techniques for the diagnosis of bacterial infection. Blue rectangles highlight molecular techniques based on 16S rRNA.

16S genomics as a diagnostic tool

Modern biology is full of remarkable milestones. One of the most transforming landmarks was the pioneering work of [Woese and Fox \(1977\)](#), who remodulated the Tree of Life and defined an entirely new branch ([Woese and Fox, 1977](#)). Through the phylogenetic analysis of 16S ribosomal RNA (16S rRNA), Woese and Fox described the domain of Archaea, a new domain in a triple-branched Tree of Life composed of Archaea, Eubacteria and Eukarya domains ([Woese and Fox, 1977](#)). Up to this point, the classification of organisms almost exclusively relied on morphological and physiological features and basic dichotomies which present several limitations ([Woese and Fox, 1977](#); [Woese, 1987](#); [Woo et al., 2008](#)). The use of 16S rRNA information proposed by Woese and Fox overcomes some of them.

The 16S rRNA is found in the 30S subunit (small subunit, SSU) of prokaryotic ribosomes in both Archaea and Eubacteria, and is homologous to the 18S rRNA found in the 40S subunit of cytosolic ribosomes of eukaryotes ([Poehlsgaard and Douthwaite, 2005](#); [Liu and Fredrick, 2016](#)). It is majorly responsible for the structure of the ribosomal SSU and is a key player in the assembly of the ribosome, namely in the binding of both 50S and 30S subunits ([Liu and Fredrick, 2016](#)). Furthermore, its 3'-end recognizes the Shine-Dalgarno sequence (ribosome binding site in Eubacteria) and it plays an important role on the peptide elongation step, thus being vital on protein synthesis ([Powers and Noller, 1993](#); [Sahu et al., 2013](#); [Amin et al., 2018](#)). These pivotal functions lead to a strict selective pressure for the conservation of some 16S rRNA gene or 16S rDNA (and, consequently, for 16S rRNA) regions, resulting in a canonical organization of the 16S rRNA gene with a conserved backbone harboring 9 hypervariable regions ([Chakravorty et al., 2007](#); [Wang and Qian, 2009](#)). Taking *E. coli* as example, the 1541 bp-long 16S rRNA gene (J01695.2) ([Brosius et al., 1978](#)) has its nine hypervariable regions (V1 to V9) spanning nucleotides 69–99, 137–242, 433–497, 576–682, 822–879, 986–1043, 1117–1173, 1243–1294 and 1435–1465, respectively ([Cannone et al., 2002](#); [Chakravorty et al., 2007](#)) (Figs. 3 and 4). The 16S rRNA gene is omnipresent in Eubacteria with conserved function and different regions of the gene change at various (but still slow) rates allowing for its use as molecular chronometer or molecular-clock ([Woese, 1987](#); [Tsukuda et al., 2017](#)).

Numerous 16S rRNA gene sequences are available in public databases allowing for the achievement of a strong and deep identification of organisms of interest. Among the public databases, EzBioCloud ([Yoon et al., 2017](#)), Greengenes ([DeSantis et al., 2006](#)) and Silva ([Quast et al., 2013](#)) are the most widely used ([Park and Won, 2018](#)). Additionally, the Ribosomal Database Project, RDP, contains a wide set of aligned and annotated bacterial 16S rRNA gene sequences (among other organisms) ([Cole et al., 2014](#)).

The omnipresence in the Eubacteria domain, the significant length for bioinformatics purposes, the structure containing both conserved and hypervariable regions (thus having significant species-distinguishing power), the molecular-clock character and the vast amount of data publicly available in databases make the 16S rRNA gene one of the most extensively used molecular tools for bacterial identification and phylogenetic studies.

As an established molecular vehicle for bacteria identification, 16S rRNA genomics can play a significant role as a diagnostic tool ([Janda and Abbott, 2007](#); [Woo et al., 2008](#); [Lau et al., 2015](#); [Rizal et al., 2020](#)). Bacterial identification for microbiological diagnosis is of major importance, among other reasons, for (i) distinguishing colonizer or contaminant bacteria from real pathogens; (ii) for better tailoring of antimicrobial therapeutics in terms of antibiotic choice and duration; and, at a wider level, (iii) for clarifying the epidemiology of disease-causing bacteria ([Lau et al., 2015](#)). As mentioned above, standard procedures for bacterial identification in

Fig. 3 Secondary structure model of the *E. coli* 16S rRNA (Konings and Gutell, 1995). Variable regions are identified by different colors. Image available at (and modified from) <https://crw-site.chemistry.gatech.edu/> (accessed September 2021) (Cannone JJ, et al. (2002) The comparative RNA web (CRW) site: An online database of comparative sequence and structure information for ribosomal, intron, and other RNAs. *BMC Bioinformatics* 3: 2).

clinical context require bacterial culture and subsequent analysis (Mancini et al., 2015; Guido Marcello et al., 2016; Rizal et al., 2020). Nowadays, this procedure is highly optimized and accurate for classification of bacteria commonly found in medical scenarios and presenting typical phenotypic profiles but can be regarded as limited under certain conditions (Lau et al., 2015). As reviewed by Woo et al. (2008), such conditions in which 16S rRNA genomics can be useful include the identification of uncommon bacteria (Schröttner et al., 2016; Mishra et al., 2020), bacteria with unusual or variable phenotypic profiles (Petti et al., 2005), slow-growth or uncultivable bacteria (Liu et al., 2015; Mishra et al., 2019; Satilmis et al., 2019), culture-negative infections (Rampini et al., 2011; Godfrey et al., 2020) and bacteria requiring special growing conditions regarding nutrients and/or atmosphere (Justesen et al., 2010; De Melo Oliveira et al., 2013). Given these limitations, the use of 16S rRNA genomics presents

Fig. 4 Schematic representation of 16S rRNA gene. Using the example of *E. coli*, the 1541 bp 16S rRNA gene (J01695.2) (Brosius et al., 1978) is shown and the 9 hypervariable regions (V1–V9) are presented in green with the locations reported by Chakravorty et al. (2007). Yellow regions represent the conserved backbone of 16S rRNA gene. The annealing region of the universal bacterial primers 8F, 27F and 1492R is depicted with black arrows (F and R point to forward and reverse primers, respectively; the number refers to the 3′-end annealing position of each primer on the *E. coli* 16S rRNA gene). The annealing region of commonly used NGS primers for Illumina, Nanopore and PacBio technologies is pointed with gray arrows. It should be noted that Nanopore technology makes use of the universal 27F and 1492R primers. A 100 nucleotide-long scale is presented.

a solid and reliable alternative allowing for bacterial identification from clinical contexts in a culture-independent manner, surpassing some limitations of more traditional methods, and standing out as an advanced diagnostic tool compatible with the expected medicine for the 21st century. It has also been suggested that, when possible, biochemical analysis and 16S rRNA genomic approaches should be used complementarily (Godfrey et al., 2020; Somerville et al., 2020).

The establishment of 16S rRNA was indeed a transforming step for modern biology, with special potential as a diagnosing tool, thus several approaches are used—and are always arising—in order to better use it for the clarification of biological problems. The most important approaches for retrieving 16S rRNA data are described and deepened below.

16S genomic approaches

Conventional PCR and primer choosing

The first typical approach to access 16S rRNA is DNA sequencing after conventional end-point polymerase chain reaction (PCR) targeting the 16S rDNA. End-point reverse-transcriptase polymerase chain reaction (RT-PCR) directly targeting the 16S rRNA molecule was also described and suggested as more sensitive due to the multiple copies of 16S rRNA molecule in a cell when compared to the number of 16S rRNA genes (Kempsell et al., 2000). Conventional PCR was itself a reshaping tool of modern biology, leading to a Nobel Prize in Chemistry (1993) for its major driver, Dr. Kary B. Mullis, awarded along with Dr. Michael Smith. Briefly, PCR is a molecular biology technique for exponentially amplify a region from a DNA template (Mullis et al., 1986), relying on an in vivo genome replication-mimetic in vitro process. It consists in multiple cycles of a step for template DNA denaturation through heating, followed by the annealing of short oligonucleotides (called primers) that prime a third step of chain elongation by DNA polymerase using the target DNA region as template (see Caetano-Anollés, 2013 for further details). In addition to this, RT-PCR includes a prior reverse transcription step, using adequate primers and a reverse transcriptase enzyme that synthesizes complementary DNA (cDNA) using RNA as a guide and allowing it to be used as a template as in a regular PCR (see Bachman, 2013 for further details).

The conserved- and hypervariable-region organization on 16S rRNA gene turns it into an attractive target for PCR amplification aiming at assessing sequence variability as the conserved regions can anchor universal primers for the amplification of several hypervariable regions (and spanned conserved regions) in different bacteria (Chakravorty et al., 2007) (Fig. 4). A recent work, however, have shown that these “conserved” regions are not so conserved as previously assumed, leading to issues in the usage of “universal” primer sets (Martinez-Porchas et al., 2017). Although hypervariable regions show significant variability, no single hypervariable region sequence can be used as universal bacteria distinguisher (Chakravorty et al., 2007). Despite this, each hypervariable region can be used to distinguish specific pathogenic bacteria within a certain group: for example, region V1 showed potential for distinguish between non-pathogenic *S. aureus* and pathogenic coagulase-negative staphylococci, while V2 seemed promising in discerning species from *Mycobacterium* genus (Chakravorty et al., 2007). The same study suggests that a combination of several hypervariable regions, namely V2, V3 and V6, could be used for bacterial identification to genus and species level (Chakravorty et al., 2007).

As an established molecular tool, a wide set of primers is described for bacterial 16S rRNA gene or 16S rRNA cDNA amplification. For conventional end-point PCR, the most used primers set is 27F (5′-AGAGTTTGATCMTGGCTCAG-3′) and 1492R (5′-GGTACCTTGTTACGACTT-3′), based on the primers firstly proposed by Weisburg et al. (1991). Alternatively, 8F (5′-AGAGTTTGATCCTGGCTCAG-3′) (Turner et al., 1999) is used as forward primer jointly with the mentioned 1492R. These primer sets, depicted on Fig. 4, are considered universal, thus amplifying the 16S rRNA gene of virtually all bacteria, even with descriptions of inter-kingdom amplifications (Galkiewicz and Kellogg, 2008). Despite this, some amplification failures were also reported and may lead to results bias (Farris and Olson, 2007). The use of 8F/27F and 1492R primers results in the amplification of

On the primer descriptive, F and R point to forward and reverse primers, respectively; the number refers to the approximated annealing position of each primer on the *E. coli* 16S rRNA gene. Some primers present degenerated positions that are pointed as W (weak, either A or T), S (strong, either G or C), Y (pyrimidine, either C or T), R (purine, either A or G), M (amino, either A or C) and K (keto, either G or T).

almost the entire 16S rRNA gene, spanning hypervariable and conserved regions, whose sequencing provides data allowing for significant distinguishing power and statistical validity (Claridge, 2004; Chakravorty et al., 2007).

Other technical approaches using gene amplification or a lesser necessity for distinguishing power usually require or allow smaller amplicons. With this in mind, several primers have been described to anneal in different regions of the 16S rRNA gene and can be easily matched to retrieve amplicons with the features of interest regarding size and spanning of conserved and hypervariable regions. New primers and new modifications are frequently suggested, though mainly focusing in alternative approaches (Sambo et al., 2018; Isla et al., 2021; Kameoka et al., 2021). By way of example, some established universal primers for bacterial 16S rRNA are presented on Table 1.

Typical workflows for 16S rRNA analysis through conventional PCR consist of Sanger sequencing of the 16S rRNA gene amplicons (Sanger et al., 1977), followed by sequence curation and querying against the previously mentioned 16S rRNA databases (DeSantis et al., 2006; Quast et al., 2013; Cole et al., 2014; Yoon et al., 2017), or the conventional broad-use databases with BLASTn (Boratyn et al., 2013; Lau et al., 2015). While this approach is historically relevant and may be relatively simple and low-cost, it has been gradually abandoned by researchers in favor of high throughput approaches that are analyzed further below.

Quantitative real-time PCR

The evolution of molecular biology, in particular the evolution of nucleic acids extraction techniques and broad-range PCR amplification methods, provides tools to detect faster any kind of bacterial DNA present in a sample, even during the earliest phase of infection, which would otherwise remain undetected. In addition, sequencing of the amplicon generated by broad-range PCR allows subsequent identification of the organism, as the PCR product contains variable bacterial species-specific sequences. These sequences can be identified by comparison with known sequences deposited at GenBank or other databases (Wilson et al., 1990; Drancourt et al., 2000). As discussed above, several broad-range PCR assays have been reported in the literature and the majority of these assays use primers targeting the 16S rRNA gene (Wilson et al., 1990; Drancourt et al., 2000; Warwick et al., 2004; Renvoisé et al., 2013). However, because of their high sensitivity, broad-range PCR is vulnerable to contamination and may result in false-positive results (Millar et al., 2002). Contamination can be brought by DNA from the environment, from PCR reagents or due circulating cell-free DNA from dead bacterial DNA controlled by the immune system or by an efficient anti-infectious therapy (Opota et al., 2015).

Quantitative real-time PCR (qPCR) has revolutionized the way clinical microbiology laboratories diagnose bacterial pathogens (Klaschik et al., 2002; Bankowski and Anderson, 2004; Mackay, 2004). Indeed, the introduction of qPCR-based offers other advantages, including (i) a fast and high-throughput detection and quantification of target DNA sequence; (ii) the multiplexing of amplification of several targets into a single reaction; (iii) the detection of specific genes and alleles (e.g., detection of resistance (or virulence) traits); and (iv) a higher sensitivity and specificity compared to the conventional PCR. qPCR method combines PCR chemistry with fluorescent probe detection of amplified product in the same reaction and allows the prevision of a test result much sooner than for conventional PCR, in an hour or less. Additionally, quantification is also useful in the case of infections with different pathogens in order to determine the infection severity and relative abundance of each pathogen, helping to identify possible contamination (Rello et al., 2009). Sensitive and specific detection is possible by using a fluorescent probe. Three types of nucleic acid detection methods have been used most frequently with qPCR testing platforms in clinical microbiology: (i) 5' nuclease

(TaqMan probes), (ii) molecular beacons and (iii) fluorescence resonance energy transfer (FRET) hybridization probes. Briefly, TaqMan probe is a short oligonucleotide (DNA) that contains a 5' fluorescent dye and 3' quenching dye. When the probe is intact and the fluorescent dye is in close proximity to the quencher dye no fluorescence is emitted. During polymerization, Taq DNA polymerase (with a 5'-exonuclease activity) cleaves the 5'-end of the TaqMan probe, separating the fluorescent dye from the quenching dye and generating a light signal. The cleaved (free) fluorescent dye accumulates after each PCR temperature cycle, and can be measured at any time during the PCR cycling (Holland et al., 1991). Molecular beacons are similar to TaqMan probes. These probes also have a fluorescent dye on the 5'-end and a quencher dye on the 3'-end, which are designed to be complementary at low temperatures, exhibiting a characteristic stem-loop structure. At high temperatures, the central region of the molecular beacon probe binds to the PCR product and forces the separation of the fluorescent reporter dye from the quenching dye, creating the light signal (Tyagi and Kramer, 1996). On the other hand, FRET hybridization probes are two DNA probes designed to anneal next to each other in a head-to-tail configuration on the PCR product. One probe has a fluorescent dye donor on the 3'-end, while the other probe has an acceptor dye on the 5'-end. In the absence of a specific DNA, the two probes do not align together and FRET does not occur. But when both probes anneal to the target DNA, fluorescence from the 3' dye is transferred to the adjacent acceptor dye on the 5'-end of the second probe, and the acceptor molecule emits fluorescence (Clegg, 1995). Molecular beacons and FRET hybridization probes, unlike TaqMan probes, are both recycled at the end of each PCR cycle; however, fluorescent signal does not accumulate at the end of each PCR cycle.

Several commercially qPCR instruments are available and support all or some of the dyes described above (Table 2). Quantitation of target nucleic acid is possible with any of the instruments and supported detection formats (Espy et al., 2006).

Instruments which allows to read microplates with more than 96 wells are particularly useful in clinical laboratories which process a large number of samples. These instruments include the Applied Biosystems™ QuantStudio series and ViiA 7 Real-Time PCR System; LifeScience Roche Roche LightCycler® 480 System; and Biorad CFX Touch and Opus Systems in their CFX384-versions. Whereas large-capacity instruments support high number of samples but have a slow thermocycling, low-capacity instruments permit a rapid thermocycling and a flexibility that may be suitable for laboratories that test fewer samples.

The target primer sequences must be unique in order to identify a specific organism or an organism group. Although out of the scope of this chapter, qPCR may also be used to identify unique virulence genes or genes or mutations associated with antimicrobial resistance (Peker et al., 2018). The target nucleic acid sequence should also be conserved in the organism to be identified and quantitated, and the laboratory test must consistently produce accurate and precise results to assure a validated test (see Espy et al., 2006 for further details). The use of qPCR using 16S primers have been described in the detection of bacterial pathogens (Meddeb et al., 2016; Okolie, 2017; Liu et al., 2018), including neonatal sepsis (Ohlin et al., 2008; İstanbullu et al., 2019; Oeser et al., 2020), infective endocarditis (Marín et al., 2007; Faraji et al., 2018), periprosthetic joint infection or septic arthritis (Yang et al., 2021), infectious endophthalmitis (Ogawa et al., 2012), amniotic fluid (Girón de Velasco-Sada et al., 2018), and bacterial meningitis (Deutch et al., 2006; Chen et al., 2009).

In summary, the qPCR allows to increase the detection rate of microorganisms, improving the sensitivity of detection, providing results in a short time, and lowering the risk of contamination (Waggoner and Pinsky, 2016; Yagupsky, 2017). Furthermore, it tends to be used as a standalone technique, i.e., without a further DNA sequencing step. Thus, due to the high specificity of qPCR, specific primers tend to be used for microorganism identification instead of primers targeting the 16S rRNA.

Table 2 Example of real-time PCR instruments used in clinical laboratorial context.

<i>Instrument</i>	<i>No. of samples</i>	<i>Probe supported</i>	<i>Manufacturer</i>
LightCycler® 2.0 System	32	FRET, molecular beacons, TaqMan	LifeScience Roche
LightCycler® 96 System	96		
LightCycler® 480 System	96 up to 384		
GeneXpert® Xpress Systems	2 up to 14	Molecular beacons, TaqMan	Cepheid
GeneXpert® Infinity Systems	40 up to 80		
Rotor-Gene 3000	72	FRET, molecular beacons, TaqMan	Corbett Research
Applied Biosystems™ QuantStudio Real-time PCR	96 up to 384	TaqMan, molecular beacons	
Applied Biosystems™ 7500 Real-Time PCR Systems	96		BioRad
Applied Biosystems™ StepOne and StepOnePlus Real-Time PCR Systems	48 up to 96		
Applied Biosystems™ ViiA 7 Real-Time PCR System	96 up to 384		
CFX96 Touch Real-Time PCR Detection System	96	FRET, molecular beacons, TaqMan	
CFX384 Touch Real-Time PCR Detection System	384		
CFX96 Dx Real-Time PCR Detection Systems	96		
CFX96 Opus Real-Time PCR Systems	96		
CFX384 Opus Real-Time PCR Systems	384		
QuRapID-XF	4	Molecular beacons, TaqMan	BioGene

Hybridization techniques

Techniques based on hybridization also allow the identification of microorganisms based on the 16S rRNA gene. Namely, fluorescent in situ hybridization (FISH) is a technique suitable for the detection of pathogens in positive blood cultures. In this hybridization assay, slides of positive blood cultures are prepared and fluorescently labeled oligonucleotide probes are used to specifically bind to the ribosomal RNA (rRNA) region in the genome of targeted pathogens (to the 16S rRNA gene of bacteria, or to the 18S rRNA gene of fungi). This specific binding between the probe and its complementary sequence is visualized by fluorescence microscopy (Paolucci et al., 2010).

FISH assay can identify more than 95% of bacteria and yeasts commonly found in blood in 2.5–3 h (Oliveira et al., 2001; Kempf et al., 2005). Although FISH technology allows for the identification of most bacteria and yeast commonly found in blood, no species-specific probes are available and some bacteria can only be identified at the genus level (Paolucci et al., 2010).

A FISH method using a peptide nucleic acid probe (PNA-FISH) (AdvanDx, Woburn, MA, United States) was the first test for *S. aureus*. This commercial kit is still available by the name of *Staphylococcus* QuickFISH BC (OPGEN, USA). Other two similar kits, such as *Enterococcus* QuickFISH BC and Gram-negative QuickFISH BC are also available by the same manufacturer. This PNA probe targets 16S rRNA to directly identify *S. aureus* from positive blood culture within 3 h (Oliveira et al., 2002; Chapin and Musgnug, 2003). This assay has also been extended to other bacterial and fungal pathogens, such as *Candida albicans*, *E. coli* and *P. aeruginosa* (Sogaard et al., 2005; Shepard et al., 2008). However, this method can only be applied after Gram staining, since such information drives the choice of the kit type.

More recently, Prudent et al. (2018) evaluated the efficiency of FISH technique in endocarditis and vascular infections caused by *Coxiella burnetii*, using probes targeting *C. burnetii*-specific 16S rRNA sequence (5'-CCGAAGATCCCCGCTTTC-3') (Prudent et al., 2018). A similar work was published by Huang et al. (2019), which have developed a novel approach for accelerated detection of bacteria in blood without the subculture step, using a combination between PNA-FISH and enhanced acoustic flow cytometry (PNA-FISH-AFC) (Huang et al., 2019). They have used a 16S probe (5'-TATCTAATCCTGTTC-3') which, in combination with flow cytometer, was able to detect genetic material within intact bacterial cells, in a shorter incubation time of 5–10 h. Other works using PNA-FISH have also been published (Hansen et al., 2016; Lopes et al., 2018; Rocha et al., 2018).

Next-generation-sequencing (NGS)

Next-generation-sequencing (NGS) is a high-throughput massive parallel sequencing technology enabling the simultaneous and independent sequencing of millions of DNA fragments (Gu et al., 2019). Bioinformatics analysis of the output of NGS platforms allows a magnitude of applications that are extremely useful for the clinical microbiology laboratory, namely addressing pathogens detection and identification, as well as identifying virulence determinants or antibiotic resistance genotypes. An additional advantage includes the possibility of simultaneous analysis of several genes (or even all genome) (Yohe and Thyagarajan, 2017). The NGS costs continuous declining is turning this powerful technology accessible to the clinical microbiology laboratories. Indeed, high-throughput genomics is joining the big-data club as massive amounts of sequencing data keep to be produced. From 1982, the number of bases in Genbank double approximately every 18 months. The number of bases available by whole-genome-sequencing (WGS) surpassed the number of bases available by Genbank in 2004, while the number of sequences exceeded the ones of Genbank in 2014. For downloading purposes, the uncompressed GenBank Release 244.0 requires approximately 1780 GB (Genbank release 244, June 2021). The European Bioinformatics Institute (EMBL-EBI, www.ebi.ac.uk) continually expands its total disk capacity to keep pace with demand, storing 120 petabytes (1 petabyte is 10^{15} bytes) as of November 2017 (Cook et al., 2018). Besides the problem of archiving big sequencing data, in order to obtain answers to scientific questions out of sequencing data bioinformatics, tools are absolutely necessary. Software and web servers' solutions for genomic analysis are constantly being developed. Choosing the appropriate ones will always depend on the answer that is pretended, the computing power available and the bioinformaticists skills.

The general workflow for NGS involves sample processing, sequencing and bioinformatics analysis (Schwarze et al., 2020). Sample processing starts with DNA extraction and DNA quality control, using UV-Vis measurement, fluorescence measurement and/or agarose gels. Sequencing itself depends on the NGS platform used, but general steps involve library preparation, normalization and validation followed by the NGS running. The bioinformatics step starts with a quality assessment of the DNA sequencing reads and the use of several bioinformatics tools explored below.

Different sequencing platforms options are available for NGS. Most studies use Illumina (San Diego, USA) devices (MiniSeq, MiSeq, NextSeq 550 and NextSeq 1000 & 2000) (Gu et al., 2019). Illumina uses sequencing by synthesis in which single stranded DNA fragments are attached to a flow cell (given that the adaptors added to the DNA fragments are complementary to the flow cell oligos). Next, in the clustering step, each DNA fragment is isothermally amplified, providing the reading of the fluorescently labeled nucleotides and determination of each base (A, G, T, or C). Illumina has high throughput and presents as pitfall barcode index switching, which may lead to incorrect sample assignment during flow cell scanning (Gu et al., 2019). Another platform available is the Ion Torrent from Thermo Fisher Scientific (Waltham, United States), which uses semiconductor sequencing technology. Here, single stranded DNA molecules are cloned on a bead within an emulsion PCR (analogous to the 454 sequencing, Roche). In the emulsion PCR each nucleotide is applied and washed in turn and the incorporation of the nucleotide by the nascent DNA strand is measured by the difference in pH caused by the release of protons during polymerization, allowing proton detection by a metal-oxide-semiconductor present in the microprocessor. Ion torrent provides quick detection, but is less able to detect homopolymer

sequences, due to signal loss when the same nucleotide is incorporated a repeated number of times (Heather and Chain, 2016). These sequencing platforms so far presented are also known as second-generation sequencing, as opposition to the first-generation Sanger sequencing that relied on chain-termination by using the dideoxy technique. More recently, the third-generation sequencing is based on Single Molecule, Real-Time (SMRT) Sequencing used by PacBio (Pacific Biosciences, United States) and Nanopore sequencing (Oxford Nanopore Technologies, United Kingdom) (Heather and Chain, 2016). In SMRT sequencing by PacBio, adapters are ligated to the DNA forming a circular DNA that is placed in the SMRT cell. The SMRT cell have small holes named the zero-mode waveguides (ZMW). A single DNA molecule is mobilized to each ZMW and, as the polymerase incorporates labeled nucleotides, light is emitted, measuring nucleotide incorporation in real time (Eid et al., 2009). SMRT offers as advantages long reads and quick runs, while the drawback a higher error rate (Ardui et al., 2018). Finally, the Oxford Nanopore Technologies (Oxford, United Kingdom) through MinION, GridION, and PromethION is offering portable sequencers that can be connected to any computer that complies with system requirements. In this technology, PCR amplification is not mandatory for DNA sequencing. Instead Nanopore relies on passing a single stranded DNA by a grid of nanopores (tiny protein channels) that causes changes in the ion current allowing to determine the DNA sequence. Nanopore offers long reads and very short sequencing time, but has less accuracy (Gu et al., 2019). All of the presented technologies are revolutionizing how physicians diagnose bacterial infectious diseases, with applications from bacterial identification, to antibiotic resistance determination, or microbiome study.

Metagenomics

Metagenomics studies using NGS, the metagenomic NGS (mNGS), is a growing filed in clinical microbiology laboratories, allowing to analyze the microbial load in human samples, which can be used in the diagnosis field, specially relying in the 16S rRNA gene (Schlaberg et al., 2017). The methods exposed above mostly rely on PCR that via primer specificity allow to identify a limited number of pathogens, struggling to identify multiple distinct pathogens in the same sample. The metagenomics approach allows to determine all microbiota, including of course the identification of particular pathogenic bacteria associated with a given infection. The NGS platforms presented above offer the possibility of conduct mNGS studies which can be used in several fields, including the clinical microbiology laboratory. The main advantage of metagenomics relies on not requiring culture, and allowing the identification of both known and novel microorganisms. In the metagenomics approach there is no need to search for each specific pathogen, allowing laboratories to identify bacteria from a single sequencing-based method (Miller et al., 2013). While mNGS is not the standard technique for bacterial infection identification, it is especially useful for identifying low-abundance, new, difficult to detect and co-infecting pathogens directly from clinical samples (Han et al., 2019), for which it is expectable the continuous implementation of this technique by laboratories and in clinical practice. There is still a high number of infectious diseases whose etiology remains undetermined, reaching about 50% of the cases of blood stream infectious and central nervous system infections (Robinson et al., 2013; Simner et al., 2018), which increases the use of broad spectrum antibiotics with all their pitfalls: emergence of antibiotic-resistance bacteria, treatment failure and higher mortality risk. Although outside the scope of this chapter, the use of mNGS can be extended to other applications important for the clinical microbiology laboratory, such as prediction of antibiotic resistance (Sukumar et al., 2016), identification of virulence traits (Levade et al., 2021), or follow up of outbreaks (Robinson et al., 2013).

All NGS platforms presented above offer protocols that can be used for mNGS, targeting a few or even all the nine hypervariable regions of the 16S rRNA gene (Table 3). Reiterating, the 16S rRNA gene is about 1500 bp long and presents nine variable regions (V1 to V9) that are extensively used for pathogen identification. The sequences between the hypervariable regions tend to be conserved and are used for universal primer design. Among pathogens, the extent of sequence diversity varies and one variable region alone is not able to distinguish all pathogens (Chakravorty et al., 2007).

Table 3 Metagenomic approach offered by NGS platforms.

NGS Platform	Primers	16S rRNA region
Illumina ^a	F-TCGTCGGCAGCGTCAGATGTGTATAAGAGACAGCCTACGGGNGGCWGCAG R-GTCTCGTGGGCTCGGAGATGTGTATAAGAGACAGGACTACHVGGGTATCTAATCC	V3, V4
Ion Torrent	Proprietary primer set V2–4-8 Proprietary primer set V3-6,7-9	V2, V4, V8 and/or V3, V6, V7, V9
PacBio ^b	F-GCATCCACTCGACTCTCGCGTAGRGTTYGATYMTGGCTCAG R-GCATCAGAGACTGCGACGAGARGYTACCTGTTACGACTT	Full length V1 to V9
Nanopore ^c	27F 1492R	Full length V1 to V9

^aThe overhang adapter sequence is in bold.

^bPacBio provides a long list of primers that may be used (8 forward primers and 24 reverse primers), only one pair is presented. For detail consult the Amplification of Full-Length 16S Gene with Barcoded Primers for Multiplexed SMRTbell® Library Preparation and Sequencing. Barcode sequence is in bold

^cPrimers described in Table 1, to which barcodes and 5' tags are added.

Illumina mNGS targets V3 and V4 regions, based on the universal primers proposed by Klindworth et al. (2013). Other target rRNA 16S regions can be used by replacing the pair of primers used, but conserving the overhang adapter. Ion torrent offers the possibility to amplify 2 variable regions of the 16S rRNA gene with two pools of set V2-4-8 and V3-6,7-9 primers (primer set V2-4-8 and primer set V3-6,7-9), which can be used individually or in combination. PacBio and Nanopore allow the sequencing of the entire 16S rRNA gene (Fig. 4 and Table 3).

The introduction of mNGS in the clinical microbiology laboratory is expected to grow in the near future and has been used for the identification of pathogens (Abayasekara et al., 2017; Han et al., 2019; Duan et al., 2021) in several bacterial infections, such as dental caries (Kazemtabrizi et al., 2020), endocarditis (Oberbach et al., 2017; Kolb et al., 2019), encephalitis (Greninger et al., 2015), joint infection (Flurin et al., 2021) or endophthalmitis (Mishra et al., 2021).

The use of mNGS in clinical microbiology laboratories is however complex, requiring equipment acquisition, protocol optimization and validation, computer power and, highly trained personnel, or bioinformatics software validation (Chiu and Miller, 2019). Considering the bioinformatics analysis of the outputs of the NGS platforms, this can be performed using host computers and servers or cloud solutions. There are a few bioinformatics pipelines for mNGS analysis, like SURPI (Naccache et al., 2014), Taxonomer (Flygare et al., 2016), Centrifuge (Kim et al., 2016), Kraken (Wood and Salzberg, 2014) and IDseq (Kalantar et al., 2020). The use of mNGS is expected to be more and more fast, accurate, cheap and easy to use in the clinical microbiology laboratory, and may come to replace current techniques used for pathogen identification.

Conclusions

Infectious disease caused by bacteria is an important cause of death worldwide and the diagnosis of these microorganisms is challenging. Traditionally, detection and identification of bacterial infections relied solely on culture-based techniques and blood culture has been considered the “gold standard” for pathogen detection. Standard culture techniques depend on morphological and biochemical characteristics for identification, which can lead to decreased specificity. Only a fraction of bacteria can be successfully cultured *in vitro* due to various factors, such as fastidious growth requirements, non-viable organisms or inhibition by previous antibiotics administration.

The 16S rRNA gene is a universal gene found in all bacterial chromosomes. Methods based on identifying the presence of conserved and hypervariable regions in the 16S rRNA gene have opened an entirely new horizon for bacterial identification. Conventionally, molecular detection is still the best method of species identification in clinical samples. Molecular techniques can be performed directly on clinical samples providing a rapid detection of pathogens using DNA amplification, typically conventional PCR followed by Sanger sequencing, qPCR, or probe hybridization techniques. In summary, molecular methods explore the existence of a conserved region in the 16S rRNA gene for universal primer annealing that allows the amplification of the 16S rRNA hypervariable regions. Subsequently, after DNA sequencing and by comparison to a database of known sequences, bacteria identification is achieved. More recently, mNGS started to be introduced, allowing for the identification of the microbial genetic content in clinical samples. Importantly, 16S mNGS has the potential to revolutionize the diagnosis of IBI in hospitals with molecular biology facilities, being currently best positioned as a complementary technique to be used alongside culture and other traditional methods. Despite this, metagenomics requires skilled scientists to perform the experiments and to analyze the data which, to date, centers in the academic research environment rather than at the frontlines of public health. To be considered a clinical test for pathogen detection in a public health laboratory or hospital, standard metagenomic protocols are necessary for testing and analyzing samples and compare results.

Introduction

Mycobacteria spp. are uttered to be existed around 150 million years ago (Cambau and Drancourt, 2014). In 1720, physician Benjamin Marten, in his book named 'A Theory of Consumption,' assumed that small living creature may be responsible for transmission of tuberculosis (TB) into patients through air (Barberis et al., 2017). *Bacillus leprae* was the first known representative of *Mycobacterium* by Hansen in 1875 (Balamayooran et al., 2015; Pfyffer, 2015). In 1896, the genus *Mycobacterium* was originally erected by Lehmann and Neumann (Barberis et al., 2017; Jagielski et al., 2016). *Mycobacteria* are aerobic, non-endospore forming, rod shaped bacteria. In the cell wall of *Mycobacteria*, lipopolysaccharide is replaced by mycolic acids, results in forming waxy water resistant layer. For this reason, *Mycobacteria* cannot be stained by conventional gram staining procedure because waxy component in the cell wall prevents the absorption of aniline dyes (Pfyffer, 2015). The mycobacteria can be divided into two groups namely, slow growers, need more than 7 days for growth e.g., MTB complex that includes *Mycobacterium tuberculosis*, *M. bovis*, *M. africanum*, *M. microti*, *M. caprae*, *M. canettii*, and *Mycobacterium pinnipedii* and fast or rapid growers form visible colonies within 7 days including NTM (non-tuberculous mycobacteria) *Mycobacterium ulcerans*, *Mycobacterium haemophilum*, *M. asiaticum*, *Mycobacterium shimoidei*, and *Mycobacterium szulgai* (Pfyffer, 2015).

Mycobacterial pathogens are responsible for a number of wide spread diseases among human and animals (Paton, 2021). In 1880, Robert Koch identified the etiological agent of human tuberculosis and named it *M. tuberculosis* (Cambau and Drancourt, 2014). *M. tuberculosis* can be associated with both lungs infection and extra-pulmonary tuberculosis including intestine, meninges, lymph nodes, bones, joints, kidneys, skin and neurotuberculosis (NTB), a granulomatous infection of the central nervous system (CNS) (Peters et al., 2020). Bovine tuberculosis (BTB) caused by *M. bovis* is one of the major health problems in livestock industry. It is also the major cause of zoonotic tuberculosis (Cousins, 2001). Further, *Mycobacterium leprae* is the infectious agent of leprosy which is a chronic granulomatous disease (Mungroo et al., 2020). Clinical symptoms such as disfiguring bacterial inclusions in the skin, peripheral nerves, and respiratory mucosa are also considered as way of disease identification. Different diagnosis and detection methods are available to test leprosy. Lepromin skin test is used to determine the disease (Mungroo et al., 2020).

From the early epidemics, detection and diagnosis of *Mycobacterium* pathogens had been difficult (Mungroo et al., 2020). Along with conventional laboratory tests based on clinical features and growth in culture, the necessity of molecular detection has been urged to shorten the time limit of diagnosis (Acharya et al., 2020). Several promising diagnostic tests has been developed and are being used in many countries. Moreover, use of immunological methods for diagnosis of *Mycobacterium* has been restricted because of their low sensitivity and specificity (Anochie et al., 2012). Molecular technologies solve this problem because they have the highest sensitivity and specificity. That is why resource-rich countries prefer molecular techniques more for detection of *Mycobacterium* (Acharya et al., 2020; Anochie et al., 2012). Unfortunately, despite the availability of these advanced tools and techniques, accurate diagnosis of infection in early stage remains a problem till now (Acharya et al., 2020). Studies focusing on the molecular detection to improve the accuracy and reduce the detection time are needed. A comprehensive analysis on the present molecular polymerase chain reaction (PCR) based detection of *Mycobacterium* is required to understand the points need attention. This review focuses on the available molecular detection and diagnostic methods of *Mycobacterium* pathogens that will be a guideline to determine the scope of future analysis to improve the molecular detection.

Disease burden of *Mycobacterium* spp

Mycobacterium tuberculosis, associated with tuberculosis disease which typically affects lungs but can affect other site occasionally, transmitted through air by sneezing, coughing and even just talking. About 10 million people develop TB yearly and among them 1.6 million people die of this (WHO, 2021a). At present 198 countries and territories with 99% of the world's population, have been recorded for TB cases (WHO, 2021a). In 2019, an estimated 10.0 million (range, 8.9–11.0 million) people was infected by TB (WHO, 2021a). Geographical distribution of prevalence of TB in 2019 was 44% in South-East Asia, 25% in Africa and 18% in the Western Pacific, with smaller percentages in the Eastern Mediterranean (8.2%), the Americas (2.9%) and Europe (2.5%) (WHO, 2021a). In 2020, the COVID-19 pandemic had a negative impact on patients with TB. A collaboration study conducted by Avenir Health, Imperial College and the United States Agency for International Development (USAID), named 'Stop TB partnership' reported that a 3-month lockdown followed by 10-month restoration of services may cause an additional 1.4 million TB deaths between 2020 and 2025 (WHO, 2021a).

Leprosy is an age old disease that had been prevalent from the ancient time. The recorded first breakthrough of leprosy occurred in the 1940s. According to World Health Organization, the present estimation for global prevalence of leprosy to be over 210,000 cases annually (WHO, 2021b). Currently the prevalence of leprosy is approximately 0.34 in per 10,000 people. Moreover, in recent years 200,000 new cases of leprosy have been reported annually in more than 105 countries throughout the world. The highest rates of leprosy are in Asia and Africa (Lobo, 2006; WHO, 2021b). Underdeveloped nations are at the greatest risk, mostly in Southeast Asia, North and South America, Africa, and the eastern seaboard of the Pacific Ocean and the Western Mediterranean coast. 64% of all new cases has been recorded only in India alone (WHO, 2021b). Multidrug (dapsone, rifampicin and clofazimine) therapy has been proved effective in the treatment of leprosy (Smith et al., 2017). To eradicate leprosy worldwide, WHO has launched a program named "Global Leprosy Strategy 2016–2020: Accelerating towards a leprosy-free world" in 2016 (Sharma et al., 2020; WHO, 2021b).

Mycobacterium bovis is the causative agent of bovine tuberculosis, is also associated with the major cause of zoonotic tuberculosis. Estimation of the global burden of zoonotic TB are imprecise (Carneiro et al., 2019). Moreover, WHO estimated that there were 147,000 new cases of zoonotic TB in humans in 2016 and 12,500 deaths occurred due to the disease. Reduction of burden of tuberculosis depends on the rapidity of implementation of DOTS (directly observed therapy, short course) program (Carneiro et al., 2019).

Detection of *Mycobacterium* spp. by conventional methods

Traditional detection methods of *Mycobacterium* spp. include, direct microscopic observation and isolation through culture method (Glennon and Cormican, 2001; Pfyffer, 2015). In addition, detection through nucleic acid amplification has gained popularity recently. Still microscopic observation is a reliable method for detection of *Mycobacterium*. Bronchoscopes and related devices are widely used sources (Pfyffer, 2015). Preparation of smear and examination under microscope is still most conventional and inexpensive process. But due to waxy cell wall special acid fast staining (traditionally Ziehl-Neelsen staining) is needed to facilitate the uptake of dye (Pfyffer, 2015). Presently fluorescent stain (auramine) is preferred by many laboratories (Pfyffer, 2015). The sensitivity of staining and microscopic observation ranges from 22% to 80% (Glennon and Cormican, 2001).

M. tuberculosis produce off-white and rough colonies on solid media. Egg-based medium of Lowenstein-Jensen was used previously for the culture of mycobacterium but the process is slow (Pfyffer, 2015). At present, commercially available culture systems marketed for the isolation of mycobacteria are MGIT (BD) and MB Redox (Heipha Diagnostica Biotest, Heidelberg, Germany), semi-automated systems (the BACTEC 460TB system; BD) and fully automated systems e.g., the BACTEC 9000MB and BACTEC MGIT 960 (BD), the ESP Culture System II (Trek Diagnostic Systems, Westlake, Ohio) and the MB/BacT ALERT 3D system (Pfyffer, 2015). *M. tuberculosis* and some species of *M. bovis* are easily recognized by its susceptibility to pyrazinamide. *M. leprae* has an important exceptional characteristic that it cannot be cultured in vitro (Pfyffer, 2015). A short insight of available tests to detect *Mycobacterium* spp. is given in Fig. 1.

Immunological tests

Many rapid tests have been developed based on different principles of immunological test reactions (Pinto et al., 2012). These rapid tests have shown varying degrees of sensitivity and specificity but due to low level of specificity most of the immunological tests are not recommended in developed countries (Pinto et al., 2012). Use of immunological test for the detection of *Mycobacterium* is confined only in low and middle income countries with weak regulatory systems. Evidence shows that commercial kit for the detection of pulmonary TB were inconsistent with 10–90% sensitivity and 47–100% specificity (Pinto et al., 2012). Lipoarabinomannan, cord factor, A60, 38 kDa, and 16 kDa are antigens that been used so long for antibody detection kits. The sensitivity and specificity respectively 15.7% to 89.2% and 50% to 100% has been recorded for such antibody tests (Singh and Grover, 2011). Besides, for the detection of antigens in sputum, CSF, pleural fluid and ascetic fluid different techniques such as RIA, EIA, hemagglutination, and latex agglutination has been used in laboratories (Singh and Grover, 2011). Most common immunological tests are antibodies from lymphocyte secretion (ALS) assay, transdermal patch, tuberculin skin test, Mantoux skin test, Heaf test and adenosine deaminase (ADA) tests (Pfyffer, 2015).

Fig. 1 Short insights into the available diagnostics methods used to detect *Mycobacterium* spp., particularly *Mycobacterium tuberculosis*.

Tuberculin skin test

Tuberculin test also known as positive purified protein derivative (PPD) skin test is the first developed immunodiagnostic test (Pfyffer, 2015). The standard recommended tuberculin test is the Mantoux test (Pfyffer, 2015). It is based on the fact that infection with *M. tuberculosis* bacterium produces a skin reaction caused by delayed-type hypersensitivity to certain components of the bacterium (Pinto et al., 2012). The test is inspected for the evidence of redness, swelling and induration after 48–72 h of administration. The result is interpreted based on the measurement of the diameter of the zone of induration (Pfyffer, 2015).

Enzyme-linked immunosorbent assay

Sandwich ELISA (sELISA) and dot-ELISA are two notable ELISA techniques also used for the antigen detection. Lipoarabinomannan (LAM) has been most frequently used as the target antigen, and its monoclonal and polyclonal antibodies have been used to detect antigen in sputum samples (Pfyffer, 2015). A study for the diagnosis of tuberculosis in Indian population used an indirect ELISA based technique (Kashyap et al., 2007). They presented a prospective evaluation for detecting Antigen (Ag) 85 complex in the sera from TB patients. Monoclonal antibodies (mAb CS-90) against the purified Ag-85 complex, was used. Ag-85 complex comprises of three related major secretory proteins of *M. tuberculosis*: Ag-85A (31 kD), Ag-85B (30 kD) and Ag-85C (31.5 kD) (Kashyap et al., 2007). To perform the test, in sera from TB patients, Ag-85 complex was incubated with mAb(CS-90). About 197 different groups of patients were included in this study. The test yielded 82% sensitivity and 86% specificity for TB diagnosis (Kashyap et al., 2007).

INF-gamma release assay

A recent approach for the detection of latent TB infection has been developed called IGRAs (INF-gamma release assay). The test measures release of IFN-gamma from T cell, in response to antigen which is unique to MTB, including early secreted antigenic target 6 (ESAT-6) and culture filtrate protein 10 (CFP10). Though IGRAs and TST are based on similar mechanism, IGRAs is more specific than TST. Commercially two IGRAs are available: the QuantiFERON-TB © Gold In-Tube (QFT-GIT) assay (Cellestis Ltd., Vic., Australia) and the T-SPOT.TB © assay (Oxford Immunotec, Abingdon, United Kingdom). Specificity (>95%) of IGRAs has been recorded for detection of latent TB infection (Pinto et al., 2012).

QuantiFERON-TB gold

Quanti FERON-TB Gold (Cellestis Limited, Carnegie, Victoria, Australia) which detects the release of IFN-gamma in fresh heparinized whole blood collected from sensitized persons (Acharya et al., 2020). Blood is then incubated with synthetic peptides that stimulates ESAT-6 and culture filtrate protein-10 (Acharya et al., 2020). The test is commonly used in developed countries as an alternative to TST. This kind of test is justified for patients who have had known exposure of MTB, HIV infection, and existing immunocompromised conditions (Acharya et al., 2020). Blood samples are collected using MTB antigen coated tubes are used for the collection of blood. IFN-γ release is measured using Enzyme Immunoassay (EIA) technique. The QuantiFERON-TB Gold In-Tube is exactly the same test overcoming the limitations of QuantiFERON-TB Gold (Acharya et al., 2020).

T-SPOT.TB

In T-SPOT.TB (Oxford Immunotec Limited, Abingdon, United Kingdom, 2008) test, peripheral blood mononuclear cells is incubated with mixtures of peptides (ESAT-6, CFP-10). To detect increases in the number of cells that secrete IFN-gamma, an enzyme-linked immunospot assay (ELISpot) is used (Acharya et al., 2020; Anochie et al., 2012; Singh and Grover, 2011).

Molecular detection techniques

Molecular detection techniques has opened a new era in the detection of *Mycobacterium*. Due to poor reliability of serological tests, molecular techniques are a must (Pfyffer, 2015). Before the invention of molecular genetics methods, the identification of *Mycobacterium* was difficult and time consuming. Recently, rapid advances have been made in the molecular detection methods of *Mycobacterium* (Glennon and Cormican, 2001). Nucleic acid amplification tests (NAAT) of *Mycobacterium* are mainly based on the polymerase chain reaction (PCR) methods.

Nucleic acid amplification

The greatest advantage of nucleic acid amplification tests (NAAT) is the rapidity of result (within hours). Along with PCR, another two amplification techniques, transcription mediated amplification (TMA) and strand displacement amplification (SDA) are commercially used widely (Glennon and Cormican, 2001; Pfyffer, 2015). These tests have a level of 98–100% specificity and 92% sensitivity. Not only sputum but also blood, lymph, CSF, urine and bronchial aspirates can be used in NAAT methods to detect *Mycobacterium* spp. The main disadvantage of this technique is the high price and complexity (Pfyffer, 2015).

Polymerase chain reaction

Desired DNA sequence is amplified by PCR and detected even when a limited number of desired organism is available in the sample (Pfyffer, 2015). The most common targeted sequence for *Mycobacterium* in PCR is the insertion sequence IS6110. Other target genes include MBP64, rpoB, and hsp65. IS6110 is a 1355 base pair long fragment that encodes four enzymes required for its own transposition and insertion and is flanked by imperfect 28-bp inverted repeats. This is a unique sequence for mycobacteria which is present for about 20 times in the genome. In 2012 a comparative study has been performed in Bangladesh among 100 clinically suspected TB patients using Lowenstein-Jensen medium and PCR targeting IS6110 from sputum sample and reported 100% specificity and 94.74% sensitivity (Bifani et al., 2009; Deggim-Messmer et al., 2016).

Previously a *Mycobacterium* genus probe for detection of NTM DNA in clinical specimens using the COBAS™ TaqMan™ platform was developed (Deggim-Messmer et al., 2016). A *Mycobacterium* genus TaqMan™ probe was designed (5'-Cy5-CGACAAACCACCTACGAGCTCTTACGC-BBQ-3'). QIAquick PCR purification Kit (Qiagen, Hombrechtikon, Switzerland) was used for the purification of CP b 45. Another used primer for 16S rRNA gene sequencing is Mbakt-14 (5'-GRG RTACTCGAG TGG CGA AC-3') (Deggim-Messmer et al., 2016). A study from July 2003 to June 2005 was conducted in Victoria, Australia to detect the causative agent of Buruli ulcer, *M. ulcerans*. The study results in the development of a TaqMan assay targeting IS2404 multiplexed PCR (Fyfe et al., 2007). The assay had shortened the time limit and conventional gel-based PCR for laboratory confirmation of *M. ulcerans* infection (Fyfe et al., 2007). They analyzed 415 clinical specimens and demonstrated 100% sensitivity and specificity compared with culture. Along with this, another multiplex TaqMan assay targeting IS2606 and the ketoreductase-B domain of the mycolactone polyketide synthase genes of *M. ulcerans* was designed to analyze variety of environmental samples (Fyfe et al., 2007). Different primers used to detect different species of *Mycobacterium* are given in table 1.

TMA: Transcription mediated amplification is based on the principle to determine unique genetic information. In this amplification technique, RNA amplicon is detected through hybridization protection assay (HPA) (Ramachandran and Paramasivan, 2003).

SDA: Strand displacement amplification is an isothermal DNA amplification reaction based on a restriction endonuclease nicking its recognition site and a polymerase extending the nick at its 3' end, displacing the downstream strand (Acharya et al., 2020; Anochie et al., 2012).

AMPLIFIED MTD Test: AMPLIFIED MTD (*Mycobacterium tuberculosis* direct) Test (Gen-Probe, Hologic) is a specific test to detect amplified rRNA of *M. tuberculosis* directly. This is a rapid process with 96% sensitivity and 100% specificity (Acharya et al., 2020; Anochie et al., 2012).

LCR: Ligation chain reaction is a DNA amplification technique, based on two adjacent synthetic oligonucleotide primers that binds only with one strand of the target DNA and the another pair of oligonucleotide hybridize to the complementary DNA (Acharya et al., 2020; Anochie et al., 2012).

Xpert MTB/RIF: On the basis of Cepheid Gene Xpert system, the xpert MTB/RIF test is designed to detect *M. tuberculosis* and its resistance to rifamycin automatically. Targeting 81 base pair core region of rpoB gene, a hemi nested real time PCR assay is used. This method is simple with lower biohazard risk, robust and rapid (90 min) (Acharya et al., 2020). The test sensitivity has been proved 98%. In a systematic review, Li and colleagues analyzed 52,410 samples from 106 studies and reported an overall pooled sensitivity of Xpert MTB/ RIF at 0.85 (95% CI 0.82–0.88) and specificity at 0.98 (95% CI 0.96–0.98) as compared to culture and concluded that the Xpert MTB/RIF provides rapid and effective diagnosis of tuberculosis (Acharya et al., 2020). In Fig. 2, the flow chart of detection of *Mycobacterium* from patients with active and latent TB is given.

Genotyping methods

PCR based genotypic methods are newly developed including spoligotyping, IS6110-based RFLP (Restriction fragment length polymorphism) and mycobacterial interspersed repetitive unit (MIRU) typing (Acharya et al., 2020; Anochie et al., 2012). These genotyping methods are rapid and conventional. But possibility of returning into false positive result has decreased the use of these techniques (Acharya et al., 2020; Anochie et al., 2012).

Spoligotyping: A recently developed method, spacer oligonucleotide typing or spoligotyping, has been introduced for the detection and typing of MTB complex (Gori et al., 2005). The method is based on amplification of a highly polymorphic direct repeat locus in *M. tuberculosis* genome by PCR. In this locus, a variable number of short, direct repeats are interspaced with non-repetitive spacer sequences (Gori et al., 2005). Variation in number of different isolates are used to obtain different hybridization patterns and then hybridized to multiple synthetic spacer oligonucleotides. The result is obtained rapidly, not only detection but also strain identity can be identified. In comparison with culture results, the sensitivity & specificity of spoligotyping was 98% & 96% for clinical specimens while 91% sensitivity & 98% specificity for slides obtained from liquid medium, and 100% sensitivity and 94% specificity for slides obtained from colony on Lowenstein-Jensen solid medium (Gori et al., 2005).

RFLP: Restriction fragment length polymorphism is the most widely used DNA finger printing method. For *M. tuberculosis* insertion sequence IS6110 is used as genetic marker. RFLP based on IS900 is widely used to characterize different MAP (*Mycobacterium avium* subspecies *paratuberculosis*) strains (Acharya et al., 2020). In this process DNA fragments of various length is produced by digestion with restriction endonuclease. These fragments are subjected to gel electrophoresis on agarose gel and fragments of different size are separated. Followed by southern blotting and DNA probe hybridization, desired fragment bearing IS6110 is detected by observing banding pattern. IS6110 based RFLP is a standard genotyping method approved by international community that serves both inter and intra-laboratory detection system (Acharya et al., 2020). The standard method include-*Pvu* II (restriction endonuclease) for *M. tuberculosis* genomic DNA digestion, 3' fragment of IS6110 as hybridization probe, standardized molecular weight marker for IS6110-based RFLP (Acharya et al., 2020). IS6110 is stable enough that it is sufficient to identify the sequence to determine same strain spreading from one patient to another. Another important characteristic of IS 6110 is its diversity. These two criteria (stability & diversity) makes IS6110 a suitable epidemiological marker. Because the relatedness certain strains can be compared studying this (Acharya et al., 2020). In previous studies the primers RIS3, 5'-CGTCGAACGGCTGATGACCA-3' and 6110-R, 5'-GGCGGGTCCAGATGGCTTGC-3' have been used for the amplification of the IS 6110 probe from chromosomal *M. tuberculosis* DNA. Universal primers such as T7 can be used to amplify IS 6110 fragment from pUCIS (Bifani et al., 2009).

MIRU: Mycobacterial interspersed repetitive units (MIRU) are mini-satellite sequences of 77–101, 46–53 and 58–101 bp in length, consist of short tandem repeat structures which is found at multiple loci throughout the *M. tuberculosis* genome (Bull et al., 2003). MIRU were first identified in *M. tuberculosis* (MTB). Recently, it has been used for typing Mycobacterial pathogens such as *M. tuberculosis*, *M. bovis* and *M. avium*. For the characterization and distinction of MTB complex MIRU is being used widely with PCR (Bull et al., 2003). A study was performed where *M. avium* species were distinguished using MIRU. There was MIRU identified at 18 conserved loci throughout genome of the *M. avium* subspecies *paratuberculosis* (MAP) and *M. avium* subspecies *avium* (MAA). Among the 18 loci, 6 loci were found to differ between MAA and MAP in the number of tandem repeat motifs occurring at each MIRU locus (Bull et al., 2003). Primers used to amplify these loci are given in Table 2.

Fig. 2 Flow diagram showing the order of diagnosis for the non-infected, patients with latent infection and active infection. TB, tuberculosis; TST, tuberculin skin test; NAA, nucleic acid amplification assays; CT, computed tomography; TPT, tuberculosis preventive treatment; IGRA, interferon gamma release assay.

LAMP: Loop-mediated isothermal amplification (LAMP) method for the diagnosis of active TB disease has been recently endorsed by WHO. LAMP is a simple, rapid, specific and cost-effective NAA method performed in peripheral laboratory settings, was developed by Eiken Chemical, Japan (Acharya et al., 2020). In this method, at least four different sets of primers are specifically designed to recognize at least six distinct regions of the target gene. Only a single step is required for amplification by strand displacement reaction. It takes 15–60 min at ~65 °C temperature. Visual inspection of the incorporated fluorescence is used to detect amplicons (Acharya et al., 2020). The greatest advantage of LAMP method is, it does not need any expensive special reagents or sophisticated equipment for result interpretation. Operational feasibility of using this method has been evaluated and implemented successfully. The sensitivity and specificity of this method was recorded 76–80% and 97–98% respectively (Acharya et al., 2020).

LPA: Line probe assay (LPA), another PCR based assay used to detect *M. tuberculosis* and drug resistance mutations. In the test, respective sequence is amplified using PCR and subsequent hybridization on a strip immobilized with specific oligonucleotide probes. The presence of *M. tuberculosis* is determined by visual observation of the colored bands. There are different versions of commercial products based on the principle of LPA, for example, commercially used line probe assays are-INNO-LiPA Rif TB kit (Innogenetics, Zwijndrecht, Belgium), GenoType MTBDRplus 1.0 (Hain Lifescience, Nehren, Germany) and MTBDRplus 2.0 test (Hain Lifescience, Nehren, Germany) (Acharya et al., 2020).

Whole genome sequencing: Whole genome sequencing (WGS) is the next-generation sequencing (NGS) technology that determine complete nucleotide sequence of a microorganism. NGS based technology like WGS are used for characterization of the organism, drug susceptibility testing, genotyping and epidemiological investigation. Whole genome sequencing also provides an advantage of pursuing mutation analysis compared to other methods (Glennon and Cormican, 2001).

M4, Forward	5'-CGTTCAGCCTGTGCATGG-3'
M4, Reverse	5'-CAAGTCGTCACGGGCAAC-3'

Radiography

Various radiographic techniques are used to directly assess the damage in the infecting organ specially, in lungs by *M. tuberculosis*. Among the radiography methods, Chest X-ray, CT scan, abreuography and FDG PET/CT are most common. Chest radiographs can accurately suggest abnormalities but are not confirmatory diagnostic of TB. Cavities in the upper lobe created by TB becomes visible in X-rays (Rossi et al., 2005). The CT scan can reveal active and disseminated TB namely miliary TB by imaging the tiny nodules scattered throughout the lung. Further, FDG PET/CT can be used for a wide range of diagnosis focusing the detection of active TB, differentiation between active and latent disease, determination of stage, and treatment response monitoring, and identification (Pelletier-Galarneau et al., 2017). In Table 3 all the possible sites of non-TB and TB infection in patients with appropriate tests are described.

Diagnostic approaches other than conventional methods

Chromatography: Chromatography is the technique for separating components in a mixture based on differential affinities of substances. In the detection of *M. tuberculosis*, chromatography is used to differentiate between species on the basis of the length of colic acid residues in the cell wall. The result can be interpreted rapidly within 2 h (Anochie et al., 2012).

TB PNA FISH: PNA FISH stands for peptide nucleic acid fluorescence in situ hybridization assay is based on a unique DNA (PNA) which binds with DNA probe where sugar phosphate backbone has been replaced by polyamide allows differentiation between tuberculous and nontuberculous mycobacteria which is determined by fluorescence. Sensitivities for MTB complex specific PNA probes has been recorded 84–97% while the NTB specific PNA probes has showed 64–91% sensitivities (Ramachandran and Paramasivan, 2003).

MPB 64 patch test: MPB 64 is an antigen specific for *M. tuberculosis* complex. The patch test result can be determined within 3–4 days and its application lasts for a week. The sensitivity and specificity is 87.8% and 100% respectively (Ramachandran and Paramasivan, 2003).

FAST Plaque TB: FAST Plaque TB (BIOTEC Laboratories Ltd., FIND—Foundation for Innovative New Diagnostics) is a unique type of test where mycobacteria-phages are used to infect *Mycobacterium* and indirectly determine its presence. After infection with phage, clearing zones or plaques indicates a positive result. The phages are destroyed later with virucide without affecting host bacterial cells. The result is as rapid as available within 24 h. But the major limitation is it can only detect live *Mycobacterium*. The sensitivity and specificity has been recorded 70.3–75.2% and 98.7–99% respectively for this test (Anochie et al., 2012).

Conclusion

The disease burden of *Mycobacterium* is still one of the major health problems globally. Early and accurate detection of *Mycobacterium* with high sensitivity and specificity can lessen the risk of developing severe disease. To avoid false diagnostic results, the necessity of efficient diagnostic tools are unavoidable. Although, conventional methods based on microscopy and serology are easy to perform but have not been proved much effective. For the rapid and error free detection, PCR based molecular methods has gained popularity. Molecular detection of *Mycobacterium* spp. by PCR based methods has been proved more rapid and efficient in recent studies and the specificities have been recorded 88.9–99.2% while sensitivities have been recorded 63.7–95.9% (Kakhki et al., 2019). However, the high cost of these tests are one of the major problems including the fact that they supplement conventional methods rather than replacement in developing countries. Lack of adequate trained and skilled stuff is another shortcoming. It is evident that even today detection of *Mycobacterium* in a cost effective way remains a problem. Development of new systems, overcoming the costing and human resource issues is demanded.

Table 3 Site-specific diagnostic tests available for both non-respiratory and respiratory TB (Acharya et al., 2020; Tuberculosis, 2011).

Organ/System	Specimens	Radiography	Microbiological approaches	Molecular methods	Biopsy
Bone/joint	Bone marrow, joint fluid ^a	Plain X-ray, CT and MRI	Microscopy, AFB smear test, conventional culture, drug susceptibility, rapid culture	NAA assays, Xpert MTB/RIF assay, Xpert MTB/RIF ultra assay	Site of disease
Central nervous system	Cerebrospinal fluid	CT brain and MRI	Microscopy, rapid culture methods	Xpert MTB/RIF ultra assay	Cerebrospinal fluid
Disseminated	Bronchial wash, bone marrow, blood ^a	CT and ultrasound	Conventional culture, drug susceptibility, rapid culture	Xpert MTB/RIF ultra assay	Bronchial wash, bone marrow, blood
Gastrointestinal	Ascites	CT abdomen and ultrasound	Conventional culture	Xpert MTB/RIF ultra assay	Biopsy
Genitourinary	Early morning urine ^a	Intravenous urography and ultrasound	Conventional culture, drug susceptibility, rapid culture	Xpert MTB/RIF ultra assay	Site of disease, endometrial curettings
Larynx	Sputum ^a	X-ray and CT	Conventional culture, rapid culture	Xpert MTB/RIF ultra assay	Site of disease
Liver	—	Ultrasound	—	—	Site of disease
Lungs	Pericardial fluid, sputum ^a	X-ray and CT	Conventional culture, drug susceptibility, rapid culture	Xpert MTB/RIF ultra assay	Site of disease
Lymph node	Aspirate ^a	—	Conventional culture, drug susceptibility, rapid culture	Xpert MTB/RIF ultra assay	Node or aspirate
Pericardium	Pericardial fluid ^a	Echocardiogram	Conventional culture, drug susceptibility, rapid culture	Xpert MTB/RIF ultra assay	Pericardial fluid
Pleural cavity	Pleural effusion ^a	X-ray and CT	Conventional culture, drug susceptibility, rapid culture	Xpert MTB/RIF ultra assay	Pleural effusion
Skin	—	—	—	—	Site of disease

CT, computed tomography; MRI, Magnetic resonance imaging.

^aImmunological tests and rapid test like immunochromatography can be applied.

Introduction

Interactions between ourselves and our bacterial communities either within us or those we interact with in our environment are inevitable, constant and necessary. For the rare events during which any of our innumerable host-bacterium interactions cause disease, medicine and the sciences of pathology and epidemiology have developed ways to detect, treat and prevent spread of at least some of these diseases. The incomplete state of the science of detecting infectious disease, coupled with relentless adaptation by clinically relevant bacteria requires ongoing research and development to try to ensure that detection methods and treatment keep developing and are effective. The evolution of clinical microbiology as a mainstream laboratory science is less than 100 years old. In the clinical laboratory there always remains a challenge between detecting the pathogen and determining (a) what treatment is likely to be effective, (b) making a timely report, (c) using finite laboratory resources optimally, and (d) ideally, fully understanding the putative pathogen's genetic potential to cause disease or to transmit harmful features to another, perhaps distantly related species. The latter objective is a specialized research activity in clinical microbiology, currently.

In particular, when following established methods for pathogen detection and characterization, it is important not to limit our understanding of the isolate's propensity to cause disease to the name and epidemiological type that it is conventionally (and technically correctly) identified by in the laboratory. There are situations where it is the presence of one or more specific genes rather than the species name or its epidemiological type that are most important but detection of these cases is hampered by conventional diagnostic laboratory methods. Where a normally sterile body site is cultured and a single isolate is found in a symptomatic patient with, for example meningitis, Koch's postulates are easily followed, but in the case of, for example, gastroenteritis, where the pathogen or pathogens must be selected from a diverse community of microbes, the investigation can be challenging.

Genomic islands or chromosomal islands are large DNA sequences found in the genomes of certain bacterial strains of a species but not in the genomes of other highly-similar strains. Genomic islands encode many different functions, which depend largely on the environmental context in which the bacterium grows. Pathogenicity islands, for example, carry clusters of virulence genes whose products contribute to the pathogenicity of the bacterium (Schmidt and Hensel, 2004).

The plasticity of bacterial genomes allows adaptation or fitness of the bacterium to colonize or to survive adversity and thereby to evolve. As an example, the genome sizes of nonpathogenic *Escherichia coli* K-12, enterohemorrhagic *E. coli* (EHEC) O157:H7 strain EDL933, and uropathogenic *E. coli* (UPEC) strain CFT073 are 4,639,221, 5,528,445, and 5,231,428 bp, respectively (Blattner et al., 1997; Perna et al., 2001; Welch et al., 2002). Any one *E. coli* genome contains about 5000 genes, and roughly two-thirds of these are found in all *E. coli* genomes, but the other third are accessory genes, found in other strains, but not all; furthermore, any one *E. coli* contains less than 10% of the total number of *E. coli* genes in the *E. coli* pan-genome (Land et al., 2015).

Notably, the horizontal spread of antimicrobial resistance is a significant problem and particularly since as few as six new antibiotics were released for use between 1985 and 2015 and resistance has already been observed to each of these (Kenny et al., 2015).

When antibiotics were first used in the 1940s to treat clinical infections it might have been predicted that the development of antimicrobial resistance during therapy was highly unlikely owing to the low frequency with which mutations occurred. Although antibiotics have reduced the mortality from infectious diseases they have not markedly reduced their prevalence. The level of antibiotic usage has far exceeded all early expectations; in hospitals, in the community, and in the veterinary industry where antibiotics have been used both to treat infections and as growth promoters. This has resulted in a strong selective pressure among bacteria to survive antimicrobial onslaught.

This example serves as a useful means to illustrate some mobile genetic elements (MGE), given that (among originally susceptible bacteria) antimicrobial resistance is regularly acquired through the acquisition of genes rather than by mutation, the latter being the rarer event. It is useful to study the functioning of these genetic elements through the medium of antimicrobial resistance testing as this tends to be a conveniently straightforward marker to detect in the laboratory.

Currently, the detection of antimicrobial resistance is usually achieved in clinical laboratories using an agar- or broth- based antimicrobial susceptibility test method. Following isolation, a fresh culture of the strain is used and antimicrobial susceptibility testing is set up to test the isolate against a panel of different antibiotics. The resultant antimicrobial resistance profile gives an indication of the degree of resistance harbored by the test isolate. Using phenotypic methods for antimicrobial susceptibility testing is routine as this allows resistance to be detected for a variety of underlying molecular mechanisms of resistance to an antibiotic and it is a relatively inexpensive and quick method, particularly when large numbers of isolates are being tested at any one time. Detection of genetic mutations through specific PCR assays is most useful when resistance to a key antibiotic is always associated with one or two mutations; the use of phenotypic methods shows the proof of the expression of all of the genetic resistance determinants, with few exceptions and therefore can be more useful as a catch-all method than using molecular-based assays. Sequencing isolates on a routine basis for susceptibility testing is not yet used as the value of a patient report lies in its timeliness, its appropriateness and its accuracy and sequence analysis is currently both more expensive than phenotypic methods and takes longer.

This article will describe the principal mechanisms by which bacteria acquire DNA via genetic elements, along with examples of how bacterial pathogens are thus created or altered and how they may be identified in the laboratory.

The acquisition of foreign DNA by bacteria

Bacteria can acquire foreign DNA (horizontal transfer) by three mechanisms: transformation (acquiring naked DNA from the environment), transduction (introduction of foreign DNA by means of a bacteriophage, i.e., the viral infection of a bacterium) and conjugation (cell to cell contact) (Bushman, 2002). The acquisition of naked DNA from the environment has been found to include MGE, which Domingues et al. (2012) reported can be a highly efficient process and can be independent of genetic relatedness between donor and recipient. The authors concluded from their experiments that natural transformation provides a much broader capacity for horizontal acquisitions of genetic elements and hence, resistance traits from divergent species than previously assumed.

In essence, there are two hierarchies of transfer—one being the MGE that can move between bacteria, such as bacteriophages or plasmids or conjugative transposons—the other being the movement of mobile genetic elements within the DNA itself via integrons or insertion sequences or non-conjugative transposons.

Bacteriophage-mediated insertion of DNA (transduction) to the bacterial cell via temperate or lysogenic (bacterio)phages

Temperate or lysogenic phages may either lyse or lysogenize infected cells. Lysogeny is the state where a host cell contains one or more prophages in which the lytic genes are repressed by the phage-encoded repressor. In this case the virus does not replicate independently and no viral particles are produced. The phage nucleic acid is reproduced in a stable fashion, often integrated within the host chromosome (Casjensm, 2003). However, a culture of lysogenic cells contains free phages due to the spontaneous conversion to the lytic cycle once in every few thousand cell divisions (Smith and Rees, 1999). In times of stress, such as starvation or any development that might damage DNA, these prophages can turn into lytic production (i.e., produce infective virions) and kill their host bacterium in a matter of minutes (Oppenheim et al., 2005). Lysogenic phages alter the biology of their hosts and, in turn, influence the surrounding community of host and non-host cells (Howard-Varona et al., 2017). Most bacterial pathogens are said to be lysogens, carrying prophages within their chromosome, in many cases more than one (Casjensm, 2003); pathogens are reported to be more likely than non-pathogens to be lysogens (Touchon et al., 2016).

The role in nature of transduction first depends on a high degree of specificity of the adsorption step in bacteriophage invasion (Courvalin, 1996). This process involves incorporation of bacterial DNA from either the chromosome or a plasmid into a phage particle during the phage lytic cycle. The phage particle then acts as a vector and transfers the bacterial DNA into the next cell that it infects, in a process that has been termed generalized transduction, exemplified by the demonstration that different pieces of DNA can be experimentally transferred in this way. Fillol-Salom et al. (2019) have shown that bacteria and generalized transducing phages cooperate to survive adverse attacks whereby the resulting cells are resistant to phage attack due to immunity provided by the integrated prophage and they are able to exchange bacterial DNA with other cells containing a similar prophage via the transducing particles.

Plasmids as genetic transfer vehicles

Plasmids are autonomous extrachromosomal replicons, consisting of double-stranded DNA. They have been found to range in size from less than 10 kb to several hundred kb (Dib et al., 2015) and are common in bacteria. They are able to maintain themselves in

the cytoplasm of a bacterium for many generations. For most plasmids, one or two copies are present per chromosome, but it may be as many as 50 or more copies for certain small plasmids. The number of copies influences the strength of plasmid-borne characteristics, especially antibiotic resistance (Clarke et al., 2019). Plasmids are almost always described as circular but linear plasmids also exist (Dib et al., 2015). In addition to the transfer of antimicrobial-encoding resistance genes, plasmids may also confer additional metabolic and virulence mechanisms on the host cell.

Conjugative plasmids differ from non-conjugative plasmids in their requirement for additional genes that can initiate self-transfer (thereby facilitating horizontal gene transfer) and also tend to be larger. As plasmids, these elements are extra-chromosomal double stranded DNA (dsDNA) molecules that control their own replication ensuring their vertical transmission and, as conjugative elements, they encode all functions needed for their horizontal transfer (Smillie et al., 2010). Broad host range plasmids have attracted particular attention owing to their ability to transfer genes among phylogenetically distant host bacteria and to facilitate the transfer of other, non-self-transferable plasmids (Boon et al., 2001).

Determination of the plasmids present among bacteria in one wastewater-treatment plant (one of many studies of these settings, which provide a good example of the convergence of different environments) using 454 sequencing technology yielded plasmid metagenomics data showing antimicrobial resistance sequences against almost all the major classes of antimicrobial drugs (Szczepanowski et al., 2008). The authors point out that wastewater treatment represent habitats with ever-changing chemical and biological composition of the sewage, requiring rapid adaptation by indigenous microorganisms by means of genome rearrangements which require distinctive genetic flexibility. In a study of the IncP-1 plasmids from wastewater (Schlüter et al., 2007) the authors found that the plasmids consisted of a highly conserved backbone in contrast with an enormous diversity of accessory genes within, which they strongly suggest indicates that the plasmid backbones serve as efficient vehicles for shuttling modules encoding antibiotic, heavy metal, and disinfectant resistance, degradative capabilities and/or other accessory functions. In all plasmids identified in this study by Schlüter et al. (2007), integrons were found, suggesting that these provided the flexibility of genetic insertions. Integrons are described below in some detail.

Transposable genetic elements

Transposable genetic elements can translocate from one area of the bacterial chromosome to another, or between the chromosome and a plasmid or bacteriophage DNA (Mayer et al., 1995). Transposons generally range in size from 2.5 kb to 60 kb and usually possess long terminal inverted repeats and one or several accessory genes that confer an advantageous phenotype to their bacterial host (Darmon and Leach, 2014). DNA transposition is one of several enzyme-catalyzed mechanisms by which a discrete segment of DNA is moved; there tends not to be a requirement for extensive homology between DNA sequences at the ends of the mobilized DNA segment (the transposon) and the site into which it is moved (the target site) (Hickman and Dyda, 2016). DNA transposons have been identified in essentially all genomes that have been sequenced (Hickman and Dyda, 2016). Most transposable elements have two features in common, namely inverted repeats at their ends and a central sequence that contains at least one gene encoding a protein, transposase whose function is to create DNA strand breaks at the boundary of the inverted repeats and the flanking sequence of the original donor location (Dyson, 1999). Selection of the target site by a transposable element is a function of the transposase and differs at the level of sequence specificity and stringency (Darmon and Leach, 2014).

There are two types of transposable elements, both similar, referred to as transposons and insertion sequences (IS). Transposons differ from IS in that they carry a recognizable phenotypic characteristic such as an antibiotic resistance marker (Hickman and Dyda, 2016). An IS is a relatively small (0.7–2.5-kb) DNA segment. It contains one or two open reading frames (ORFs) encoding only proteins responsible for functions involved in its mobility (a transposase) and is bounded by short terminal IR sequences (Darmon and Leach, 2014). Transposable elements are dependent on the host chromosome, plasmid or bacteriophage for regeneration (Mayer et al., 1995).

In summary, transposons can be either conjugative or non-conjugative; conjugative transposons can be defined as elements encoding their own excision, their transfer by conjugation and their integration, regardless of mechanisms (Bellanger et al., 2014), in contrast to non-conjugative transposons.

Integrins and mobile gene cassettes

Antibiotic genes of Gram-negative bacteria are often situated on plasmids and transposons. In the early 1980s, studies using restriction mapping and heteroduplex analysis showed that different sets of antibiotic-resistance genes were sometimes found in the same location in otherwise closely related plasmids such as the IncW group, or transposons of the Tn21 family (Stokes and Hall, 1989; Recchia and Hall, 1995). Further work showed that this third mechanism of antibiotic-resistance gene dissemination involved naturally-occurring gene expression elements called integrins (Stokes and Hall, 1989). These structures operate as vehicles for the acquisition of resistance genes carried by MGE, termed gene cassettes, by a site-specific recombinational mechanism (Hall and Collis, 1995) as shown in (Fig. 1). While integrins are found on many different plasmids and transposons, one integrin, Tn402, has been identified to be itself an active transposon (Bennett, 1999; Domingues et al., 2012). Class 1 integrins are most associated with clinical infections. The presence of integrins has been reported most often in Gram-negative bacteria but they also occur in Gram-positives, including staphylococci (Li and Zhao, 2018) streptococci (Lin et al., 2017) and enterococci (Clark et al., 1999; Yu et al., 2017). Yu et al. (2017) and Lin et al. (2017) experimentally observed class 1 integrin mediated excision and integration of various exogenous antibiotic resistance genes using a collection of plasmids and *Enterococcus faecalis* and *Streptococcus pneumoniae*, respectively. Interestingly, retrospective analyses have indicated that integrins were associated with resistance genes present in the

Fig. 1 Structure of a class 1 integron, including a gene cassette encoding resistance to aminoglycosides (*aadA2*).

shigella isolates that characterized the first wave of transferable plasmid-mediated resistance in Japan in the 1950s (Liebert et al., 1999).

Structure and function of class 1 integrons

Integrons, as shown in Fig. 1, comprise two conserved segments, the 5'-conserved segment (CS), which is located upstream from the gene cassette(s) and 3'-CS, which is found downstream of the resistance gene shown as an example in this figure. There is an internal variable region containing one or more gene cassettes, with a recombination site, termed the 59-base element, which includes the motif GTTRRRY (Hall et al., 1991). The 5'-CS contains the *int* gene, which encodes integrase, a site-specific recombinase. One of its substrates is the 59-base element and the second substrate is the cassette receptor or integration site (*attI1*) within the integron. Fig. 1 includes the *aadA2* gene, encoding aminoglycoside resistance, as one example. Also present on the 5'-CS are promoters required for expression of all downstream gene cassettes. The 3'-CS carries several open reading frames (ORFs), including a defective gene encoding resistance to ethidium bromide and quaternary ammonium compounds (*qacEΔ1*) and another encoding resistance to sulfonamide (*sul1*).

Cassette-associated genes are very widespread, which suggests that they play a major role in the development of antimicrobial resistance on a global level. Gene cassettes are known to have been original constituents of the first resistance plasmids reported in the mid-1960s (Bennett, 1999). Gene cassettes have been isolated from a strain of *Vibrio metschnikovii* cultured in 1888, demonstrating their predating the antibiotic era (Mazel et al., 1998). These mobile elements or gene cassettes differ from transposons in a number of ways—firstly, they do not include any genes encoding their transfer functions to a new location; secondly, cassettes are not flanked by inverted repeat sequences and thirdly, mobilization involves a conservative site-specific recombination event rather than transposition (Recchia and Hall, 1995). In terms of molecular organization and compared with, for example, conjugative transposons, integrative phages and integrating plasmids, gene cassettes are simpler in structure. Gene cassettes include only a single gene, thus differing from conjugative transposons, integrating bacteriophages (which encode both bacteriophage proteins and replication functions) and integrating plasmids. The integron is able to incorporate an antibiotic resistance gene either chromosomally or extrachromosomally. Gene cassettes may exist as free, circular, non-replicating DNA molecules when moving from one genetic locus to another but are normally found as linear sequences that constitute part of the larger DNA molecule.

The genetic elements described above should not be considered in isolation from one another. A review paper by Guédon et al. (2017) describes mechanisms by which integrative genetic elements, that may contain integrons, encode their own excision and integration and are able to hijack or subvert the mating apparatus of conjugative elements (plasmids or transposons) to promote their intercellular transfer.

Taking a closer look for levels of integration of MGE with one another, Fig. 2 (Che et al., 2019) shows the results of combining Oxford Nanopore and Illumina metagenomics sequencing to uncover the antimicrobial resistance gene context of influent, activated sludge, and effluent of three wastewater treatment plants when seeking to identify the hosts of these genes. The results showed that most of the genes detected in all three compartments of the treatment plants were actually carried by plasmids.

Considerations when it comes to the detection of MGE in clinically relevant bacteria.

Case studies are provided as illustrations throughout the next section of the chapter. The first case study shows how bacteriophages can convert different serotypes of *E. coli* to become enterohemorrhagic strains and that the extent of the diversity of serotypes that

Fig. 2 Genetic location of antibiotic resistance genes predicted from nine Nanopore metagenomic datasets of environmental samples, whereby distribution and abundance of antibiotic resistance genes in transposons and integrons located on plasmids is shown on the left and in transposons and integrons on chromosomes on the right. MLS, Macrolide-lincosamide-streptogramin; ICE, Integrated and conjugative elements. From Che Y, Xia Y, Liu L et al. (2019) Mobile antibiotic resistome in wastewater treatment plants revealed by nanopore metagenomic sequencing. *Microbiome* 7(1): 44.

have been found to cause disease has only become apparent with the advent of molecular methods in clinical microbiology laboratories. However, a considerable follow-up investigation still follows that initial molecular detection. This is important for epidemiological purposes to determine, for example the extent of an outbreak but also for a reason shown in case study 2.

This second case study discusses the challenges of using selective culture methods to grow an elusive and rare pathogen whereby the replacement of primary culture with primary molecular detection of a plasmid-borne virulence factor is very helpful. However, recombination events may also occur and the notion of what constitutes a pathogen deserves more study than the author demonstrated in the isolate being described in this example!

Case study 3 demonstrates how a mutation in the cryptic plasmid of *Chlamydia trachomatis* (a pathogen which causes the most common sexually transmitted infection in humans) caused a large proportion of false negatives when it occurred, perhaps suggesting that commercial manufacturers of diagnostic kits should target more than one locus simultaneously in their assays. The particular difficulty with generating false negatives for *C. trachomatis* is that the infection is often silent while its morbidity can be severe.

Case study 4 shows how the acquisition by Vancomycin Resistant Enterococci (VRE) of a clonal complex enhances a strain's survivability and that plasmids and transposons, extrachromosomal and chromosomal locations have all been identified as the means to harbor this advantageous addition. In a collection of otherwise quite diverse VRE strains, all had acquired clonal complex 17 in a study in Ireland, where VRE is a particular problem in hospital patients.

Case study 5 shows how epidemiological typing using (bacterio)phages may show strains of the same serotype of salmonella as being indistinguishable from one another but that the presence of integrons in these strains can provide varying numbers and types of resistance genes, suggesting that definitive phage typing is not synonymous with a defined antimicrobial resistance profile.

The final case study is chosen to illustrate the diversity of bacteria in which a particular resistance determinant—in this case TetO, which is just one mediator of resistance to tetracycline has been found in at least 11 separate genera of bacteria, both Gram-positive and Gram-negative. The transmission of this resistance is through MGE.

Case study 1: Verotoxigenic *Escherichia coli*

The genetic element-borne virulence factors may be a more suitable target for detection of the pathogen than conventional culture. The following case study illustrates how national reporting of a pathogen was affected by the adoption of a molecular mode of detection becoming widespread among diagnostic laboratories.

Verotoxigenic *Escherichia coli* (VTEC, also called Shiga-like toxigenic *E. coli* or STEC) can cause diarrhea, hemorrhagic colitis and hemolytic uremic syndrome in humans (Page and Liles, 2013), the latter being a very serious complication. The primary reservoir of VTEC is ruminants, and sporadic outbreaks are commonly associated with animal contact, exposure to animal feces, food and water contamination, and person-to-person transmission (Snedeker et al., 2009).

The key virulence factors in VTEC are stx1 and stx2 toxins (one or both may be present in a strain of VTEC, stx2 being the more commonly detected in symptomatic patients) which are borne on temperate lambdoid phages. These phages are heterogeneous, having different DNA structures and Pulsed-Field Gel Electrophoresis (PFGE) types (García-Aljaro et al., 2009). Induction to the lytic cycle results in liberated virions causing transduction of stx genes to susceptible bacteria and thus can lead to the emergence of new VTEC pathogens by horizontal gene transfer (Allison, 2007). A study by Rahman et al. (2018) of 47 VTEC O:157 strains from food and animal sources found that 10.6% of the strains produced complete phage particles capable of infecting multiple bacterial hosts.

Originally characterized in the 1980s in *E. coli* serotype O:157, the focus to detect VTEC was based on isolation and serotyping suspect colonies from feces samples from patients having symptoms and signs indicative of VTEC intoxication. This approach was labor-intensive, particularly as *E. coli* is normally found in the gut and mixed cultures were to be expected. It was discovered subsequently that the large majority of *E. coli* O:157 strains were non-fermenters of mannitol, so a selective formulation of MacConkey agar was developed that incorporated mannitol in place of lactose (and then was added tellurite and the antibiotic cefixime to add further selectivity), whereby the scientist was then looking out for pale colonies to investigate further using anti-O:157 antiserum and biochemical identification. This imperfect approach led to only selecting for VTEC that were non-sorbitol fermenting and of one serotype, also necessitating sending suspect VTEC to a reference laboratory for toxin studies. Some improvements to detection were introduced by using chromogenic agar, which generated colored colonies for different serotypes (including O:157), with varying sensitivity rates. There was the possibility of sending feces samples directly to the reference laboratory but this introduced a delay in diagnosis, particularly if the reference laboratory happened to be in a different part of the country from the investigating laboratory.

With the advent of molecular detection methods detection based on the primary detection of toxins stx1 and stx2, notifications began to rise. Fig. 3 shows a survey conducted in Ireland in 2015 (Rice et al., 2016), where the adoption of molecular methods by eight large diagnostic laboratories (using a commercial molecular assay) resulted in a dramatic increase in total (human) VTEC notifications. The O:157 detections did not vary markedly during the years studied (2010–14), which is not surprising, given that the culture-based efforts had been previously concentrated mainly on finding that serotype but there was a dramatic increase in VTEC of serotypes other than O:157, which was shown to be consistent with adopting the molecular detection approach.

In this case, the approach of making the detection of the stx genes direct from feces allows the negative majority of samples to be reported quickly as NOT DETECTED and the initial positive indication for VTEC to be notified quickly as a suspected positive result, followed up by a full laboratory investigation. In our laboratory this approach shortened the time to reporting a negative result by up to 96 h and provided a means for a same-day reporting of either a negative or a provisional positive result.

Fig. 3 Effect on VTEC notifications in Ireland of a gradual conversion by eight large clinical laboratories from a culture/serotyping-based Verotoxigenic *E. coli* O157 detection method from human stools to a molecular-based stx toxin gene detection method. From Rice T, Quinn N, Sleator RD and Lucey B (2016) Changing diagnostic methods and increased detection of Verotoxigenic *Escherichia coli*, Ireland. *Emerging Infectious Diseases* 9: 1656–1657.

Case study 2: Abandoning primary culture in favor of the molecular detection of a virulence factor borne on a plasmid of a human-to-human transmitted pathogen that is difficult to detect on culture

Shigella spp. and the plasmid-borne *ipaH* genes

The genus *Shigella* spp. is differentiated into four species: *S. dysenteriae*; *S. flexneri*; *S. boydii* and *S. sonnei*. All are pathogenic to man, causing bacillary dysentery of varying severity and all have Invasive plasmid antigen H (*ipaH*) genes, both on their large plasmid and integrated to the chromosome. Conventional culture-based detection is challenging as shigella can be difficult to isolate from the other gut bacterial flora present, being often present in small numbers in the stool sample of the infected patient (the infectious dose is also very low). The molecular detection of a conserved *ipaH* sequence has revolutionized the detection of shigella infection, whereby a positive PCR signal signifies the presence of *Shigella* spp. and follow-up work can be conducted to identify the organism to species level and serotype (by culture or molecular methods). It is worth noting that enteroinvasive *E. coli* also carries the *ipaH* gene(s). EIEC are strains that possess some of the biochemical characteristics of *E. coli* and have the ability to cause dysentery using the same method of invasion as shigella does (van den Beld and Reubsaet, 2012). Sequencing of multiple housekeeping genes indicates that EIEC is more related to shigella than to non-invasive *E. coli* (van den Beld and Reubsaet, 2012). In this case the detection of the pathogen is more important in the symptomatic patient and the decision as to whether EIEC and shigella should be reclassified has not been made.

As an addendum to this case study, when the author was testing the stool sample of a patient who had returned from a holiday in India and who needed hospitalization because of having severe dysentery, a positive *ipaH* signal indicated the presence of *Shigella* spp. Retrospective and multiple attempts to isolate shigella on the appropriate enteric culture media failed to yield a shigella isolate but a large mucoid colony was always present on every culture, which was identified as a *Klebsiella pneumoniae*. A colony *ipaH* PCR designed to produce a 600 bp product gave a positive *ipaH* signal and sequence analysis of the product showed a hybrid of the *ipaH* target flanking an internal sequence that showed complete homology to *Klebsiella pneumoniae*, suggesting that a recombination event had occurred. Whether this isolate was capable of causing the dysentery in the patient could not be concluded but no other bacterial, viral or parasitic pathogen was found, despite intensive effort.

Case study 3: Detection of chlamydia trachomatis urogenital infection via its cryptic plasmid—A mutation causing false negative test results

Chlamydia trachomatis (*C. trachomatis*) is the most common bacterial cause of sexually transmitted infection worldwide (Jones et al., 2020). This pathogen is an obligate intracellular bacterium, which often causes asymptomatic infection, may cause pelvic inflammatory disease (PID), ectopic pregnancies, scarring of the fallopian tubes, miscarriage, and infertility when left untreated (Vasilevsky et al., 2014). More than 35 years ago, a 7.5 kb cryptic plasmid was described for chlamydia (Lovett et al., 1980). Despite the evidence for significant contributions by the plasmid to chlamydial pathogenicity, there is also strong evidence that the chlamydial pathogenicity may also depend on factors that are unrelated to the plasmid (Zhong, 2017).

The plasmid is less important for chlamydial growth in vitro than during infection in vivo, suggesting that chlamydia may have acquired the plasmid for promoting its survival in animals, implicating a plasmid-dependent pathogenicity (Zhong, 2017). Nucleic Acid Amplification Tests (NAATs) are the method of choice for diagnosis of chlamydia urogenital infection (usually PCR-based) and these are targeted on the detection of the cryptic plasmid. NAATs are currently the most sensitive tests to detect chlamydia. These tests also have a high specificity comparable to culture, but in contrast to culture, do not depend on viable pathogens, facilitating a slower specimen transport without loss of result quality where this is necessary (Meyer, 2016). However, in 2006 a new variant of *C. trachomatis* with a deletion in the cryptic plasmid was detected in Sweden, following an unexpected 25% decrease in *C. trachomatis* infections that was noted between November 2005 and August 2006 in southwest Sweden (Ripa and Nilsson, 2006). These investigators sequenced part of the plasmid from the variant strain and found a deletion of 377 base pairs in the target area for the *C. trachomatis* NAAT tests manufactured by two prominent companies; a third commercial company's assay, targeting a different sequence, was unaffected. This necessitated an urgent review by other countries of their detection methods for chlamydia and by the commercial companies who needed to change the target sequences that formed the basis for their assays.

Case study 4: Vancomycin resistant enterococci and clonal complex 17 (CC-17)

Enterococci are common commensals of the enteric tract. However, the development of resistance to glycopeptide antibiotics, including vancomycin, among *E. faecium* and *E. faecalis* has been a major concern, not least because this drug is one of few that can be used to treat Methicillin Resistant *Staphylococcus aureus* (MRSA) infection and because of the possibility of transfer via MGE among these genera which often share the same environments.

Vancomycin Resistant Enterococci (VRE) are prevalent among hospital patients and are among the most frequent causes of healthcare associated infection. One study of carriage among hospital patients in Ireland (Whelton et al., 2016) showed a prevalence rate of 34% for VRE (all *E. faecium*) in an acute hospital, all containing the *VanA* gene with a subset also containing the *VanB2/3* gene encoding vancomycin resistance. Interestingly, although epidemiological fingerprinting showed high levels of diversity, all isolates showed evidence of having acquired CC-17. This complex has evolved in stepwise fashion through genetic diversification, including mutations, but primarily through recombination, whereby this primary ancestor evolved into a meroclone of highly related genotypes, which has spread globally (Leavis et al., 2006). The complex was previously described as a lineage characterized by (1) ampicillin resistance, (2) a pathogenicity island, and (3) an association with hospital outbreaks (Willems et al., 2005). The heterogeneity of the types in the Irish study (Whelton et al., 2016) suggests an environmental pressure on VRE rather

than an outbreak or distribution of a single strain, whereupon the acquisition of the CC-17 provides a survivability advantage. Insertion sequence 16 (IS-16), which has been found to be synonymous with the presence of CC-17 and which may be found on the chromosome, on a plasmid or in both locations in the same isolate (Werner et al., 2011) provides a useful marker to detect CC-17. CC-17 may provide higher levels of genetic variability including easier acquisition of MGE that may support lifestyle in new or changing environments or ecological niches such as the hospital environment (Leavis et al., 2017). Also present in CC-17-identified strains are conjugative and non-conjugative transposons (Werner et al., 2011). Incidentally, the persistence of VRE on the dry (unenriched) material of a bed drape has been shown to be longer than 8 weeks, as evidenced by its recovery after the addition of broth to the previously inoculated material (unpublished study).

Case study 5: An example of multiple simultaneous antibiotic resistance mechanism transfer via integrons demonstrated by *Salmonella enterica* typhimurium definitive phage type 104 (DT104)

Salmonella spp. as members of the Enterobacterales family are part of the normal gut-dwelling microflora of many animals, including birds, amphibians, reptiles, wild mammals, typically showing no obvious signs of causing disease. However, salmonella carriage or infection among humans (which can be a zoonosis but human-to-human transmission also occurs; salmonella can multiply on food) or domestic animals is a major cause of concern, necessitating epidemiological tracing and salmonella eradication measures. Human infection carries a high degree of morbidity and occasional mortality, rates of both of which vary depending on the state of the host and the strain of infecting salmonella.

Laboratory detection methods for *S. enterica*

The clinical laboratory either detects salmonella from food, water or feces samples using conventional culture (agar)-based methods or through the PCR-based molecular detection of salmonella, using one or more genus-specific genes. The identification of salmonella runs to being able to differentiate the serovar (serotype, based on a combination of somatic and flagellar antigens) of which there are currently more than 2700 serovars identified.

In the case of an isolate of *S. enterica* (serovar Typhimurium), later epidemiologically characterized as DT104, an isolate was simultaneously resistant to ampicillin, chloramphenicol, streptomycin and spectinomycin, sulfonamide and tetracycline, representing five different classes of antibiotic.

A study published from Denmark by Sandvang et al. (1998) of *S. enterica* Typhimurium DT104 showed that from eight different porcine herds, eight DT104 isolates gave a variety of resistance profiles—five showed the pattern described above, two isolates were susceptible to all of these antibiotics and the remaining isolate was resistance to streptomycin, spectinomycin and sulfonamide. A second epidemiological typing method used to complement the phage typing, Pulsed-Field Gel Electrophoresis (PFGE) also showed the isolates as indistinguishable, even though they were clearly not identical on the basis of their antimicrobial resistance profiles.

Therefore, it is evident from this case study that even discriminatory epidemiological typing methods may identify a collection of strains of the same species as the same type, but these may differ on the basis of genes acquired through horizontal transmission, depending on selective pressures and opportunity for environmental (or gut-based) transfer of genetic information.

Case study 6: Persistence or increased prevalence of antimicrobial resistance determinants over time

Campylobacter spp. are the most common bacterial cause of gastroenteritis and campylobacter infection in humans is often associated with consumption of poultry, which is commonly contaminated by campylobacter as an uncooked or undercooked product. Campylobacter is part of the normal microbiological flora of the gastrointestinal tract in wild birds.

Tetracycline is an old antibiotic, relatively inexpensive and broad-spectrum. Tetracycline resistance in *Campylobacter* spp. is largely conferred by a ribosomal protection protein (RPP), TetO, capable of displacing tetracycline from its primary binding site on the 30S ribosomal subunit (Connell et al., 2003; Wilson, 2014). Campylobacter tetO can be located chromosomally but is often plasmid-mediated (Connell et al., 2003). Tetracycline RPPs are widely distributed among bacterial genera and it has been reported that the *tetO* gene exists in at least eleven bacterial genera, including four Gram-negative and seven Gram-positive genera (Roberts, 2005). The conserved acquisition of *tetO* between members of different bacterial genera indicates that conjugative plasmids, transposons, or recombination events contribute to the dissemination and maintenance of the *tetO* gene (Friis et al., 2007). The maintenance of tetracycline resistance may be mediated by some other plasmid-encoded factor, conferring a survivalist advantage (Lynch et al., 2020a). A study in Ireland of poultry campylobacter isolates (2017/2018) found that 38% of *C. jejuni* isolates were resistant to tetracycline (Lynch et al., 2020b), up from 24% reported from the year 2000 (Lucey et al., 2002). Tetracycline was banned as growth-promoter for feed animals in the 1970s (Council of the European Union, 1970) but remains the most commonly used antibiotic overall, however (Przeniosło-Siwczyńska et al., 2020). Furthermore, tetracyclines are in the main excreted into the environment unchanged after being given as a dosage (Vojtová and Urbánek, 2009). Overuse and environmental contamination with this agent undoubtedly contribute to the continuing increase in resistance rates.

Conclusion

The selected case studies above illustrate how the increasingly molecular approach to clinical laboratory-based diagnosis of bacterial disease has improved the science, while still often needing a blended approach of using phenotypic and genotypic methods. We are only beginning to understand the extent of transfer of genetic material among bacteria, and the facility provided by MGE for the

transfer of virulence factors or antimicrobial resistance genes. Being able to begin with a molecular detection and following up with retrospective culture after a positive (molecular) detection has provided greater opportunity for detection of pathogens, which in some cases might be defined by the acquisition of the mobile element rather than the species name of the bacterium.

The selective pressure on bacteria to acquire resistance to commercial antimicrobial agents is driven by overuse of the limited numbers of different antimicrobials currently available and there are enhanced opportunities provided for transfer in environments of great bacterial diversity and density, for example in the gut.

The detection of genomic islands poses a particular problem for the clinical laboratory as conventional investigations and nomenclature cannot differentiate strains of the same species unless a particular transmissible trait is being determined, such as antimicrobial resistance or a specific virulence factor.

Conventional clinical detection methods of bacterial pathogens do not currently select for MGE except in rare cases. As the use of molecular methods in diagnostic microbiology laboratories becomes more mainstream and diverse, the opportunity for a broader understanding of bacterial threats to human health presents. In an ideal world, future considerations might include a more routine examination of samples for key MGE and having the means to disable them selectively.

Introduction

The emergence of novel bacterial strains harboring resistance to antibiotics is considered as one of the most public health problems in the 21st century. Currently, several pathogenic bacteria have become MDR to antibiotics recommended by World Health Organization (WHO; www.who.int), Clinical and Laboratory Standards Institute (CLSI; www.clsi.org) and European Committee on Antimicrobial Susceptibility Testing (EUCAST; www.eucast.org). AMR of pathogenic bacteria can lead to other infections than the initial infection contracted in hospital provoking high mortality rates due to the dissemination of ESKAPE pathogens (Santajit and Indrawattana, 2016). This group of bacteria including *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* species are responsible of nosocomial infections and are characterized by high drug resistance mechanisms (Rice, 2010) due to exposure to strong selective pressures, and the indiscriminate use of antibiotics (Torres-Caycedo et al., 2019). Antibiotic resistance exhibited by bacteria can be intrinsic, acquired, or adaptive (Lee, 2019). Acquired resistance mechanism may be linked to a modification of the bacteria at the genome level by either a mutation or the acquisition of new genetic material from an exogenous source (Christaki et al., 2020). Resistance mechanisms have evolved

Fig. 1 Antibiotic resistance (AR) molecular mechanisms at right: production of drug-inactivating enzymes, target modification, efflux pump action, and bypassing the affected metabolic pathway. Antimicrobial drug targets at left: peptidoglycan synthesis inhibition, cell membrane disruption, DNA replication gene transcription and translation inhibition, and folate biosynthesis. Reprinted from Van Camp PJ, Haslam DB and Porollo A (2020) Bioinformatics approaches to the understanding of molecular mechanisms in antimicrobial resistance. *International Journal of Molecular Sciences* **21**(4): 1363. <https://doi.org/10.3390/ijms21041363>, under a Creative Commons Attribution 4.0 International License (CC BY).

from an acquired AMR gene may be present on the bacterial chromosome, plasmid or transposons carrying small genetic elements “cassettes” (Giedraitienė et al., 2011). The mechanism of action of numerous AMR genes or cellular pathways are already known (Van Camp et al., 2020) (Fig. 1).

In literature many definitions were used to characterize the antibiotics resistance patterns of bacterial strains. MDR was defined as bacteria acquired non susceptibility to at least one antimicrobial agent in three or more antimicrobial classes (Magiorakos et al., 2012; Sweeney et al., 2018). XDR was defined as non-susceptibility to at least one agent in all but two or fewer antimicrobial classes (i.e., bacterial isolates remain susceptible to only one or two antimicrobial categories) (Magiorakos et al., 2012). Major emergent and widespread AMR are β -lactamase, carbapenem-resistance, rapidly developed to extended-spectrum (ESBL) in Gram negative bacilli, resistance to vancomycin of enterococci (ERV); *S. aureus* resistance to methicillin (MRSA) (Christaki et al., 2020). Other antibiotic resistances constitute a real concern, such as resistance to fluoroquinolones, rifampicin and isoniazid by *Mycobacterium tuberculosis*, *Helicobacter pylori* clarithromycin-resistant and *Campylobacter* spp. fluoroquinolone-resistant (Dookie et al., 2018; Savoldi et al., 2018; Marroki and Bousmaha Marroki, 2019; Sack et al., 2001). In 2017, WHO published a list of bacteria for which the development of new antibiotics has become vital. The list has included the 12 families of bacteria most threatening to human health. In 2014, the data collected by WHO, showing the extent of large gaps in surveillance of this problem in several countries of the world. Furthermore, the same organization estimate more than 700,000 people die every year by infection occasioned by antibiotic resistant bacteria (Vasala et al., 2020), and more than 23,000 and 25,000 people dying as a result of infectious disease in United States and in Europe every year respectively (European Centre for Disease Prevention and Control and European Medicines Agency, 2009; Prestinaci et al., 2015). The European Centre for Disease Prevention and Control/European Medicines Agency (ECDC/EMA) estimates the cost of AMR at least EUR 1.5 billion/year. Indeed, there are several challenges in diagnostic and treatment of infectious diseases due to the epidemic bacterial antibiotic resistance. By the fact of the complexity of antibiotic resistance/susceptibility in vitro methods have been developed to predict bacterial response and achieve the appropriate therapy in vivo. Fast point of care analysis, etiological agent identification, an efficient antibiotic research and a determination of the functional dosage, would be required for an optimal antimicrobial therapy policy (Vasala et al., 2020). For diagnostics of antibiotic resistance, in vitro activity of antimicrobial agents is evaluated by AST phenotypic methods based on inhibition zone measurements or by minimum inhibitory concentration (MICs) determination. The most commonly used in clinical microbiology laboratory include diffusion, gradient, and dilution (broth and agar dilution) tests, rapid automated or commercially instrument systems and devices, MALDI-TOF MS, Single-Cell and microfluidics based methods.

While multiples standardized phenotypic methods have advanced over many decades, various non-phenotypic methods, using DNA probes and nucleic acid amplification, to detect AMR genes and mutations associated with resistance phenotypes (Tenover, 2009) have recently been developed. In a number of cases where the genotype-phenotype relationship is uncomplicated, gene based prediction has been applied in clinical practice through the use of rapid molecular tests (Van Camp et al., 2020). Molecular AMR methods are efficient direct tools, in which bacterial cultures steps, long incubation, contamination risk, and the dispersion of deadly infection are eradicated (Khan et al., 2019). Various molecular tests are available commercially to detect resistance-coding genes or resistance-associated mutations in DNA extracted from purified bacterial isolates or directly from clinical samples, for both clinical and surveillance purposes (World Health Organization (WHO), 2019). Molecular AMR detection tries to identify resistance gene, as well as mutations in and expression of these genes or their genomic signature (van Belkum et al., 2020). Depending on the mechanism of detection, four major molecular categories are commonly used: (i) Amplification-based methods; (ii) Hybridization-based methods; (iii) Immunoassays, to detect AMR gene and (iv) Whole Genome Sequencing. The chapter describes the several methods developed for diagnostic of antimicrobial resistance of pathogenic bacteria, used in clinical settings and even in point-of-care (POC). Major phenotypic AST methods, automated AST tools, MALDI-TOF MS, Single-Cell methods, microfluidic devices and principal molecular techniques used to determinate or screening accurately bacterial antibiotic susceptibility and to detect AMR are concisely discussed.

Phenotypic method

Diffusion methods

Agar disk diffusion test (DDT)

Developed in 1940 by Heatley (1944), this technique is considered as the most commonly and the oldest used for routine susceptibility testing of bacteria and fungi in microbiology laboratories. Briefly, this method standardized the variables of disk size, media, the inoculum size, temperature and time of incubation. A few colonies of organism are selected and picked from culture plate and suspended into 2 mL of sterile saline or trypticase soy broth and vortex. The density was adjusted to achieve 0.5 McFarland standard prepared through a turbidity test (Jorgensen and Ferraro, 2009). Inoculation was conducted using a sterile cotton swab by streaking the dried surface of agar plate. Petri dishes are used containing Mueller-Hinton agar and may be placed in room temperature until dry for 30 min. Then, each tested disk, with fixed concentration of antibiotics, is placed (~12 disks placed/plate) on the agar surface and gently pressed with forceps to permit the complete contact with the inoculated agar plate. For microorganism growth the plates are incubated at 35 °C for 16–18 h with simultaneous antibiotics diffusion into the agar. The inhibition diameters zones for tested microorganisms formed around each disk were measured by using a ruler or the callipers. The result for each drug obtained, after an overnight incubation, are interpreted according the criteria recommended by the Clinical and Laboratory Standards Institute (CLSI, 2017) or European Committee on Antimicrobial Susceptibility Testing (EUCAST, 2020). The result may be unregistered qualitatively by classifying the strains as susceptibility, intermediate or resistant.

Emergent paper methods

Deiss et al. (2014) developed a novel method to study the antimicrobial susceptibility assays by using paper-based portable culture devices. In this method, two antibiotics are tested in the paper-based portable culture devices to measure the antibiotic susceptibility of *Escherichia coli* and *Salmonella typhimurium* by measuring blue-colored zones of inhibited growth. AST can be also evaluated by “Microfluidic hip paper supported cell culture arrays” proposed by Xu et al. (2016). In this method the AST assays cell culture arrays and the concentration of antimicrobial agents able to inhibited the chromogenic reaction in the media by combining were combined. The result to monitor the chromogenic reaction by using a camera was realized in 15 h. Compared to the conventional Kirby-Bauer test, the results shown a similarity of 94.1% with many advantages for uropathogen testing.

Another technique using a paper-based microfluidic devices has been introduced in Martínez et al. (2007) for POC diagnostic applications. This alternative method was low-cost, rapid devise and early screening of infections. The method developed by Boehle et al. (2017), utilizing paper-based devices for detection the antimicrobial resistant (AMR) bacteria, aimed to test the presence the β -lactamase mediated resistance in environmental *E. coli* isolates. The detection of the β -lactamase expression in various strains tested demonstrated the performance and applicability of paper-based devise assay and can be used as practical alternative methods for detecting AMR to the traditional methods. Recently, in study piloted by He et al. (2020a,b,c), the use of laser-pattern paper-based microfluidic device for assessing susceptibility of *E. coli* to different antibiotics, via a simple visually observable color change, were developed (Fig. 2). Four antibiotics commonly used for treat bacterial UTIs such as *E. coli* were tested including amoxicillin, ciprofloxacin, gentamicin and nitrofurantoin. The result observed indicate the suitability of paper devise for detection of bacterial infection in the POC and as novel strategy for antibiotic prescribing.

Dilution methods

The dilution tests are considered as an in vitro standardized methods for the AST. The two approaches types generally used in dilution methods are microdilution and macrodilution (EUCAST, 2019). These methods are usually used in clinical microbiology laboratories to determine the MICs of antibiotics for several bacteria, as well as yeasts and fungus (Balouiri et al., 2016).

Fig. 2 Schematic representation of the laser-based direct-write (A) Device setup (B) Description of fabricated three-layer paper device for bacteria identification and antibiotic-resistance testing. Reprinted from He P, Katis IN, Kumar A, Bryant CA, Keevil CW, Somani BK, Mahobia N, Eason RW and Sonnes CL (2020) Laser-patterned paper-based sensors for rapid point-of-care detection and antibiotic-resistance testing of bacterial infections. *Biosensors & Bioelectronics* 152: 112008. <https://doi.org/10.1016/j.bios.2020.112008>, Copyright © 2020, with permission from Elsevier.

Broth dilution method

Broth dilution testing is one of the common methods used for AST, including macrobroth and microbroth test for determination of the MICs. The procedure elaborated for this test, involve serial prepared two-fold dilutions of antibiotic agent. Each dilution is inoculated with suspension standardized of the tested bacteria adjusted to 0.5 McFarland turbidity scale, to achieve a final concentration of the inoculum of 5×10^5 CFU mL⁻¹ or 5×10^4 CFU/well (Brown-Elliott et al., 2012; Brook et al., 2013; Balouiri et al., 2016). A volume of 0.2 mL is deposited in each well and it allows testing of antibiotics tested over a range of eight- to twofold dilutions on microtiter plate. Moreover, two antibiotic-free wells without antibiotic must be included in each microtiter plate as controls (Wiegand et al., 2008; ISO-20776-1, 2019). After well-mixing, the microtiter plate is incubate in appropriate temperature, the bacterial growth is examined visually or by automated system to determinate the MICs values. The MICs is designated as the lowest concentration of antibiotics inhibits growth bacteria. Since the several advantage of microdilution assay, this method is considered the reference standard method to determinate the MICs (Jorgensen and Ferraro, 2009). The method is low cost and small volumes of inoculum are used as well as the evaluation of multiple antibiotic agents with individual isolates. One disadvantage for broth macrodilution is the time consuming, occupation of a large amount of space and reagents and error in preparation of dilution of antibiotics agents.

Agar dilution method

Agar-dilution method is currently the reference standard susceptibility method for anaerobic bacteria. The test is performed in Petri dish to determine the MICs to multiple tested strains in single plate. Through this assay, a various antibiotics agents are prepared usually at twofold dilution series and incorporated into molten agar medium plates in different concentrations. Then inoculation of the medium with a standardized suspension adjusted to 0.5 McFarland standard containing a concentration of 5×10^8 CFU mL⁻¹ (CLSI, 2012a) was conducted. The bacteria are diluted to around 10^7 CFU mL⁻¹, and 2 μ L are spotted with multi-point into agar plates contain approximately 10^4 CFU/spot (Clinical and Laboratory Standards Institute, 2015), and one agar plate used as control seeded without antibacterial agent. After incubation in anaerobic condition at 35 °C for 16–18 h for non-fastidious bacteria and for 18–24 h fastidious organisms (Barry, 1986), the agar plates are examined by visually comparing the growth. The MICs is determined based on this test as the lowest concentration of drug tested that stopped the growth of bacteria (CLSI, 2012b; Brook et al., 2013). Currently, the agar-dilution technique is considered as the reference susceptibility testing recommended by CLSI for fastidious bacteria such as *Helicobacter* spp. and *Campylobacter* (CLSI, 2010; CLSI, 2017) and anaerobic bacteria (CLSI, 2012b), and for evaluate the antifungal susceptibility (Benkova et al., 2020). In the study conducted by Liu et al. (2016a,b), disk-diffusion and agar dilution methods used for *Neisseria gonorrhoeae* AST were compared. The result obtained demonstrated a good correlation and level categorical agreements has been obtained between the agar diffusion test and standard agar dilution method. Similar conclusion obtained by Luangtongkum et al. (2007) by comparison of agar dilution and the agar disk diffusion test applied for *Campylobacter*. The advantage of agar dilution method is its suitability when few antibacterial agents are tested against a large number of microorganisms (Barry, 1986; Liu et al., 2016a,b). One drawback of agar dilution method is time-consuming and high degree of inherent error.

Gradient tests

E-test method

E-test was a new approach for quantitative antibacterial susceptibility developed in the late 1980s by Bolmström and Eriksson (1988). The method is a simple and routine used to determine in vitro the MICs on agar medium. The antimicrobial gradient

method incorporates the principle of disk diffusion and agar dilution tests. The E-test is based on the diffusion of an antibiotic agent from a plastic strip onto an agar media to provides quantitatively rapid and reproducible MICs results for tested isolates (Baquero et al., 1992). Briefly, the surface of agar plate was swabbed with the adjusted inoculum suspensions ($1-2 \times 10^8$ CFU mL⁻¹) equivalent to a 0.5 McFarland (Evangelista and Karlowsky, 2016). Then the back of plastic strips impregnated with different and accumulative of concentration gradient antibiotics agent, corresponding to approximately 20 twofold dilutions are placed in medium surface, after inoculation with tested strain (Gajdacs et al., 2017). Many E-test strips with different antimicrobial agents can be placed in surface on a single plate containing special agar medium and then incubated in various temperature with the microorganism tested. After overnight incubation, an inhibition ellipse is seen, the E-test MICs (mcg mL⁻¹) value are read directly from the upper of the Petri dish at the point of intersection of the growth ellipse and inhibition zone with the extremity of the strip (Fig. 3). This method can be rapidly and successfully applied to test the anaerobes and fastidious bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* (Jorgensen et al., 1991).

In last decade, many studies have been conducted to evaluate the reliability and the performance of E-test method with different standardized techniques for occurrence, disk diffusion and microdilution for testing pathogen and fastidious bacteria frequently used by diagnostic laboratory. These investigations conducted on coryneform bacteria isolated from clinical samples (Martínez-Martínez et al., 1995), *Rhodococcus equi* obtained from tracheobronchial aspirates or post-mortem lung tissue from pneumonic foals (Berghaus et al., 2015), forty-six dermatophytes strains (Castro Méndez et al., 2008), 194 *Enterobacterales* and 77 *Pseudomonas aeruginosa* (Wang et al., 2020) shown a well agreement between E-test and disk diffusion methods or broth microdilution method. Some important advantages of the E-test are rapidity, simply and reliability and does not require a special equipment. The E-test method is applicable to a variety of microorganism and drug, that it offers a quantitative test of MICs result which may be interpreted easily compared to standardized methods. The limitation of E-test is the relatively expensive cost and the limited array of antibiotics.

Spiral gradient endpoint method

The spiral gradient endpoint (SGE) technique is an alternative agar dilution test used for AST of anaerobic Gram negative bacteria developed by Hill and Schalkowsky (1990). In this method, colonies from overnight culture are suspended in broth and adjusted to 0.5 McFarland turbidity, the optimized inoculum is streaked vertical and cross streaks manually or with an automated inoculator through the gradient of antibiotics agents from the center to the edge of the plate. The plates were incubated at 35 °C and the MICs were evaluated by measuring the distance of inhibition from the plate center to the endpoint of growth. In study of Wexler et al. (1996), comparison of this method and reference agar method to evaluate the MICs of anaerobic bacteria was carried out. The result obtained concluded that the SGE is an alternative method to the reference agar dilution test more precise and economic.

Pong et al. 2012, compare the SGE method with the reference standardized method for *H. influenzae*, *S. pneumoniae*, *Moraxella catarrhalis* and *N. gonorrhoeae*. The result obtained shown an excellent correlation of the MICs obtained with the reference methods and concluded that the SGE is a rapid and flexible alternative method for smaller and routine laboratories.

Fig. 3 E-Test use for MICs determination of AM, ampicillin; CE, cephalothin; PP, piperacillin; IP, imipenem; and FX, cefoxitin cefotaxime (CT) and ceftazidime (TZ) against *Escherichia coli* clinical strain harboring SHV-2. Reprinted from Baquero F et al. (1992) The E-test as an epidemiologic tool. *Diagnostic Microbiology and Infectious Disease* 15(5): 483–487. [https://doi.org/10.1016/0732-8893\(92\)90095-b](https://doi.org/10.1016/0732-8893(92)90095-b), Copyright © 1992, with permission from Elsevier.

Automated methods

Vitek 2

The Vitek 2 is one of automated systems developed in 1970s by bioMérieux, commonly used for bacterial identification combined with the AST determination. The Vitek system offers important advantages for the researcher and clinician laboratories with a high reliability of the result. This method has been easily, rapid, reducing hands on time and easy to integrate in laboratory. The VITEK[®] 2 and VITEK 2 compact are equipped with the same software for the validation of antibiotic resistance tests even for new emerging resistance. Systems Vitek 2 uses 64-well plastic reagent cassettes or AST cards containing small or microwells loaded with dehydrated media with different concentration of antibiotics testing (17–20 antimicrobial agents), including one well as control without any antibiotic. The procedure used the Vitek system need to obtained pure colonies from agar plate incubated for 18–24 h. The bacterial suspension was adjusted to 0.5 McFarland turbidity standard to achieve 10^8 CFU mL⁻¹ from overnight single colonies and then diluted to 5×10^5 CFU mL⁻¹. The bacterial suspension tested is coupled with ATS card and is automatically filled, sealed and placed into VITEK 2 instrument after incubation for 18–24 h. The Vitek was used in diagnostic laboratory for antibacterial susceptibility evaluation of Gram negative and positive pathogenic bacteria such as of *Enterobacteriaceae*, *P. aeruginosa* (Bruins et al., 2004; Romero-Gómez et al., 2012; Moles et al., 2017), *S. aureus*, *Staphylococcus* spp., *Enterococcus* spp., *Str. agalactiae*, and *Str. pneumoniae* (Ligozzi et al., 2002; Bobenchik et al., 2014). Eigner et al. (2005) has worked on 307 clinical isolates, and demonstrated that the Vitek 2 system required less manual manipulation time than the Phoenix system. The category agreement and error rate were good for both systems. The study piloted by Bobenchik et al. (2014) demonstrated the performed reliability of Vitek 2 system compared to the microdilution reference method and E-test for antimicrobial susceptibility testing of *Staphylococcus* spp. and *Enterococcus* spp. clinical isolates. Alfouzan et al. (2017), compared Vitek 2 yeast susceptibility system card with E-test method to determinate the MICs. The result shown a comparable MICs between the two methods for *Candida* spp. and considered the Vitek 2 system as a reliable alternative to E-test.

BD Phoenix™

The BD Phoenix was an automated microbiology system (BD Diagnostics, Sparks, MD) been available in Europe in 2001 and in the United States since 2004. The Phoenix microbiology system employed for identification and AST of Gram-positive and Gram-negative bacteria (Stefaniuk et al., 2003; Snyder et al., 2008). The principle of Phoenix AST is based on using oxidation-reduction reaction for detection of microbial growth. The monitoring of microbial metabolisms is achieved by the color changes of the indicator (Carroll et al., 2006). The instrument of BD Phoenix system holds up 100 tests panels and one as control panel. The panels trays containing 136 wells divided into 51 well are used for identification and 85 wells ATS side with 14–22 antimicrobial agents at specific concentrations: 51 for ID, 85 for AST (Carroll et al., 2006; Jorgensen et al., 2015). The tested strains were plated in specific media such blood Colombia agar and incubated overnight to obtaining isolate colonies. Subsequently, the adjusted inoculum concentration at 3×10^5 CFU mL⁻¹ are poured into the panels for identification and ATS section respectively. The panels trays are placed into the Phoenix instrument for ID/AST and automatically incubated for up to 18 h, and the result are read and described. Bacterial growth was determined by using modified conventional chromogenic and fluorogenic indicator substrates in the system containing dried biochemical substrates and two fluorescent control well (Carroll et al., 2006). Generally, the Phoenix system reads panels every 20 min, for up 12 h to identification and between 4 and 16 for AST (MICs value). Several studies were conducted to evaluate the performance of BD Phoenix system to determine antimicrobial susceptibility of clinical isolates compared to conventional method and automated system. The category agreements (AC) obtained were 96.5% for *Enterobacteriaceae*, 84.8% for non-fermentative Gram-negative bacteria, 98.9% for *Staphylococcus* spp., 98.0% for *Enterococcus* spp. (Eigner et al., 2005), 96% for *Str. pneumoniae*, excepted for TMP-SMX trimethoprim-sulfamethoxazole (93.4% EA), 97–100% for other streptococci strains (Richter et al., 2007) and 97.8% of IMP produce by *Enterobacteriaceae* (Yamakawa et al., 2018).

Sensititre™ system

The Sensititre system is a commercial phenotypic system product by Thermo Fisher Scientific in 1999 available in the United States with Food and Drug Administration (FDA) clearance. The Sensititre system is automated using 96-well plates format with numerous antimicrobial. Classified as broth microdilution ATS system instrument assisted based on the detection of the metabolism of the fluorogenic growth substrate by bacterial tested with diverse antibiotics and converted the fluorescent signal to the MICs by computer algorithm. In Sensititre AutoReader the MIC or ID plates are inoculated with an automated inoculation system or a handheld multichannel electronic pipette before placement in the instrument's carousel. The MICs values are determined after 18–48 h of incubation stored in the computer component of the system. Another Sensititre Autoreader introduced in United State in 1992, is the ARIS 2 × (ThermoFisher Scientific), is a fully-automated system, benchtop incubating and read the bar-codes plates. Two versions are available: the semi-automated Autoreader and fully automated, robotics-driven ARIS platform (Chapin and Musnug, 2004). In Sensititre ARIS 2 × system, MIC breakpoint and ID were achieved in 96-well plate with dehydrates serial twofold dilutions of antibiotics in each well, and can perform a combination of 192 MIC, run at same time in a single instrument (Christenson et al., 2018). Drew and Paulus (2014), compared the Sensititre microdilution to Vitek-2 and standard disk diffusion methods for the susceptibility testing of 80 *Staphylococcus* isolates. The result obtained shown a good categorical agreement (90%) between Sensititre method, standard disk diffusion methods and Vitek system. Luna et al. (2007), examine susceptibilities of 95 *Bacillus* isolates by using Sensititre method and E-test susceptibility tests. The result obtained gave that the two methods produced comparable MICs results for all antibiotics tested agents (except for trimethoprim/sulfamethoxazole). Several other

studies evaluated the performance of the Sensititre system for AST for Gram-negative and positive and yeast compared to other automated and current standard methods (Chapin and Musgnug, 2004; Avolio et al., 2008; Garza-González et al., 2010; Zhang et al., 2011; Chew et al., 2017). An Sensititre MycoTB (Trek diagnostic system), was performed for susceptibility testing of *M. tuberculosis*. The Trek MycoTB plate MIC uses 96 well-microtiter plate and antimycobacterial agents in second line (Hall et al., 2012), evaluated the performance of the Sensititre MycoTB plate for susceptibility testing of *M. tuberculosis* against first-and second line agents. The result was obtained between 10 and 14 days by using MycoTB compared to the agar proportion method which is in 21 days. Other automated phenotypic Sensititre systems available by FDA clearance are commercialized such as the Sensititre® yeastOne (Trek Diagnostic Systems, United States) which is a calorimetric yeasts panel system with oxidation-reduction indication used for yeasts susceptibility testing. In Pfaller et al. (2008), evaluated the performance of YeastOne system for antifungal susceptibility testing of 404 *Candida* spp. isolates to anidulafungin, caspofungin, and micafungin, and compared obtained results to those of CLSI broth dilution methods applied in three laboratories. The investigation revealed a similarity in the result for the two tested methods for each *Candida* species.

MicroScan WalkAway®

The MicroScan system (Siemens Healthcare Diagnostics, United States), is an automated system utilizes fluorescent technology. The autoSCAN-WalkAway system was introduced in 1986 by American Microscan. Similar to other automated system, the MicroScan have dried substrates in the wells which are rehydrated by the suspension of tested bacteria. The result of the identification and AST is detected after incubation by the pH change, and growth of bacteria in wells in presence of antibacterial agents. This MicroScan system is based on broth microdilution method and available instrument include WalkAway-40 and 60, which accommodate respectively in 40 and 96-well microdilution plates contain chromogenic substrates. The MicroScan utilizes colorimetric reading using photosensors for optical detection of bacteria in the well. The antibacterial susceptibility testing can be determined within a range of 16.8–27.8 h, depending on the bacteria specie.

They are a range of MicroScan panels (conventional, rapid and specially) on single platform. The conventional contain biochemical and chromogenic test for identification and AST of a variety of bacteria (Siemens Healthcare Diagnostics, 2011).

The WalkAway plus microbiology system is a broth microdilution method includes LabPro Information Management software. The WalkAway plus Systems is a semi-automated instrument of overnight, rapid and specialty panels utilizing 96 microwell panels. The instrument configuring models for Gram positive and negative bacteria with 40 and 60 panel capacity for medium-volume high-volume laboratories are available in three types Combo panels and Breakpoint Combo panels and MIC panels. The frequently used MicroScan panels are: MicroScan Gram Pos ID panel, MicroScan Rapid Gram Pos ID panel, MicroScan Neg Type 2, MicroScan Rapid Neg ID Types 2 and 3, and MicroScan NHID (Siemens Healthcare Diagnostics, 2011). Several studies conducted by investigators to evaluate the performance of MicroScan with other automated methods. The study conducted by Quesada et al. (2010) has for objective to evaluate the reliability and accuracy of two automated systems VITEK-2 and the MicroScan, for susceptibility testing of 113 Gram-negative rods. The result obtained shown an excellent correlation >98% between the two system and 89% for *P. aeruginosa* isolates with 0.36% of very major errors. The average time required for the two systems were 4.57 ± 1.37 for automated VITEK-2 and 18–24 h for MicroScan. Another study conducted by Bulik et al. (2010), compared Meropenem MICs and susceptibilities of Carbapenemase-Producing *K. pneumonia* isolates, by using broth microdilution, E-test, Vitek 2, Sensititre, and MicroScan methods. Results obtained for MicroScan method demonstrated, 95.6% agreement based on MIC, 2.2% minor errors with broth microdilution and no very major errors were observed. Lee et al. (2013) investigation, compared the colistin susceptibility of 213 blood stream *Acinetobacter* isolate by using Vitek 2, MicroScan automated system, and E-test methods with the agar dilution method. In this study an excellent categorical agreement (both 99.1%) was shown by using Vitek 2 and E-test, compared to 87.3% (95.7% for *A. baumannii* and 80.7% for non-*baumannii* *Acinetobacter* isolates) using MicroScan. Recently, the study conducted by Singh et al. (2019), evaluated in vitro susceptibility of carbapenem-resistant clinical Gram-negative bacterial strains obtained from several clinical samples for colistin by using MicroScan Walkaway 96 Plus system and Mikrolatest. The results shown that MicroScan WalkAway 96 Plus ID/AST have an excellent categorical agreement of 71.4% (*A. baumannii*), 85.7% (*P. aeruginosa*) and 100% (*A. junii*, *A. johnsonii*, *E. coli* and *K. pneumoniae*) compared to Mikrolatest MIC.

MALDI-TOF MS (Matrix-assisted laser desorption/ionization-time of flight mass spectrometry)

The MALDI-TOF MS was discovered in the 1980s and in the 1990s, and then used to identify surface proteins of bacteria (Truant, 2016). In recent year, MALDI-TOF MS has been introduced in clinical microbiology laboratories for the routine rapid identification based on proteomic profiles and for AST of bacteria and fungi. Since, the routine AST are based on microbial growth in the presence of many concentration antimicrobial agents and require incubation time, the MALDI-TOF is an emerging technology alternatively to phenotypic or genotypic traditional method for determinate antibacterial resistance. Compared to classical methods, this method is rapid and inexpensive, have a value impact and revolution in clinical microbiology. In MALDI TOF MS, a single colony grows in specific agar plate (Wieser et al., 2012), is deposited in sample plate preparation and is mixed to UV-absorbing matrix (Cherkaoui et al., 2010), dried and then placed into the mass spectrometer. The bacteria fixed with matrix receive an irradiation with a laser and the obtained spectra are compared to a database composed of reference spectra strains in the software database. The identification of tested strain is made with corresponding similarity scores (Truant, 2016). Four commercial types systems MALDI-TOF are frequently used for bacterial identification in clinical microbiology laboratories: MALDI-TOF instrument from both Bruker Daltonics or Shimadzu: the MALDI Biotyper (Bruker Daltonics, Germany); the Spectral Archive And Microbial Identification System (SARAMIS™) (AnagnosTec, Germany); the Andromas (Andromas, France) and the Vitek MS (bioMérieux, France)

(Vrioni et al., 2018); http://www.bruker.com/jp/products/mass-spectrometryandseparations/literature/literatureroom.html?eID=dam_frontend_push&stream=1&docID=58883; http://www.biomerieux-diagnostics.com/sites/clinic/files/9300819-002-gb-a_vitek-ms.pdf.

Currently, several methodologies are applied to terminate resistance by using ATS MALDI-TOF system. The first method is to analysis the obtained spectra of tested bacteria to determine a characteristic "resistance spectre" (Kostrzewa et al., 2013; Sparbier et al., 2012). The rapid detection of extended-spectrum β -lactamase (ESBL) producing by *Enterobacteriaceae* using MALDI Biotyper (Kawamoto et al., 2019) and by MALDI-TOF MS-based MBT STAR-BL method (Ota et al., 2019) were developed. For evaluation of antibiotic resistance another type the MBT-ASTRA method was used for AST evaluation of *Bacteroides fragilis* (Justesen et al., 2018), drug sensitivity in selected mycobacteria (Ceyssens et al., 2017) and the non-susceptibility of *Enterobacteriaceae* for gentamicin and ciprofloxacin in blood cultures (Jung et al., 2014). Currently, Maldi ToF MS is largely applied for specific detection of AMR. Among the most recent investigations, detection of AMR in Enterobacteria to Colistin, Cefotaxime, Meropenem, Ciprofloxacin and Ceftriaxone (Dortet et al., 2018; Axelsson et al., 2020; Horseman et al., 2020). Moreover, Oxacillin, Methicillin and Vancomycin AMR detection in *S. aureus* and *Enterococcus* spp. was conducted by using MALDI TOF MS tool (Horseman et al., 2020; Nix et al., 2020).

Single-cell methods for bacterial analysis

A rapid antibiotic susceptibility method has been developed based on single-cell morphological analysis (SCMA) (Choi et al., 2014). This novel SCMA technique is rapid and accurate as new imaging based ATS method. In SCMA, the antibiotic susceptibility is evaluated automatically by analysis of the morphological change using single bacteria cells to different antibacterial conditions including swelling and filament formation. The data obtained with SCMA satisfy the recommendations of the U.S. FDA. The procedure for rapid ATS test with SCMA method, involved that the cells are immobilized in channels were supervised for SCMA by time-lapse bright-field microscopy after they were mixed with the agarose and loaded into a microfluidic. The antibiotics are then loaded into the wells containing nutrients and the samples diffuse in the agarose. The perform test of ATS needs 3 h from the diffusion of antibacterial agents into the imaging region. This method was tested for 189 clinical strains, included collections extended-spectrum β -lactamase (ESBL) activity-producing *Enterobacteriaceae*, methicillin resistance (MRSA), and vancomycin-resistant Enterococci (VRE). Comparison with standard broth microdilution test shown that the total agreement for all isolates was 91.5%. Another study conducted by Choi et al. (2016), tested the immobilized *M. tuberculosis* for rapid drug susceptibility test, with fastidious bacteria, namely the disk agarose channel (DAC). The DAC system is automated with an image processing program automatically determine the susceptibility and resistance of *M. tuberculosis* used in clinical areas and the result can be obtained within 1 week.

Microfluidic based methods

Microfluidic pH sensor

Microfluidic pH sensor is rapid AST method developed by Tang et al. (2013), for monitoring the pH change of bacterial metabolism product and growth rate in culture media spiked with different tested antibiotics. Recently the microfluidics method has become a tools in clinical microbiology to monitoring the microbial resistance with very small samples. This method has been applied to measuring the inhibitory activity of antibiotics by using *E. coli* as the model bacteria adjusted at 0.5 McFarland standard. A cell density of 10^6 CFU mL⁻¹ of model *E. coli* was cultured in glucose solution with 1% of tested antibiotics (ciprofloxacin, tetracycline, azithromycin, amikacin) were introduced into the microfluidic pH sensor and incubated at 37 °C. For each sample, the reflectance spectra were monitored in real time and the MIC obtained in the microfluidic pH were compared with reference method. With this technology the result can be read in less than 2 h, thus will offer advantage of this method for studying the behavior of antibiotics.

Multiplexed microfluidic platform AST of mono- and polymicrobes

A rapid novel technologies platforms been developed for rapid analysis and multiplex AST of *E. coli* treated to four different antibiotics and combinations of them (Fig. 4). With this platform a rapid result of bacterial susceptibility of *E. coli* was taken between 2 and 4 h. Also, the analysis can be carried out with minimum volume (<6 μ L) of samples and antibiotics and realized sensitivity at a single cell level. The microfluidic platform is a based biosensor technology that relies the fluorescence detection of bacteria and antibiotic susceptibility (Mohan et al., 2013). Mohan et al. (2015), used the microfluidic approach applied to study the interactions between *E. coli*, *P. aeruginosa*, and *K. pneumonia* in presence and absence of antibiotics and their growth dynamics in polymicrobial culture in real-time on chip time-lapse fluorescent imaging monitoring bacteria interaction. Result observed shown in mixed culture, the growth dynamics of individual strain depends of the initial cells and the interaction between the strains affects the AST.

Adaptable microfluidic system for single-cell pathogen

Recently, Li et al. (2019) used the microfluidics system for rapid determination of antimicrobial susceptibility for single cell pathogenic bacteria. Li et al. (2019), used tunable microfluidics valve incorporating with real-time optimal for detection bacteria (Fig. 5). The investigation demonstrated the performance of the adaptive microfluidic system to classify the bacterial pathogen *E. coli*, *S. epidermidis*, and *M. bacteremicum*. The classification is based according to the physical shape and sizes feature

Fig. 4 Optical micrographs of the microfluidic platform for on-chip AST: (A) The device comprises an array of wells loaded with colored dyes. (B) Various concentrations of antibiotics/or different combinations of antibiotics are loaded from the wells through the fluid lines A–F (green, red, blue, magenta, indigo and colorless solutions). Loading of *E. coli* strain in the wells adjacent to the antibiotics through the G–L fluid lines (yellow solutions). (C) Control antibiotic and cell load in wells by pneumatic valves 1 (D) Antibiotics and cells are mixed in adjacent chambers by actuating mixing valves 2. This ensures good diffusion results in change colors (blue/yellow to green) in optical micrographs. Reprinted from Mohan R et al. (2013) A multiplexed microfluidic platform for rapid antibiotic susceptibility testing. *Biosensors and Bioelectronics* 49: 118–125. <https://doi.org/10.1016/j.bios.2013.04.046>, Copyright © 2013, with permission from Elsevier.

Fig. 5 Process for single-cell AST unknown bacteria in urine samples w. At first, presence of bacteria in clinical samples is confirmed. In the same microfluidic device: (i) pathogen classification of positive samples was based on the rod or spherical form and size (minimum trapping pressure); (ii) AST is conducted. Reprinted from Li H et al. (2019) Adaptable microfluidic system for single-cell pathogen classification and antimicrobial susceptibility testing. *Proceedings of the National Academy of Sciences* 116(21): 10270–10279. <https://doi.org/10.1073/pnas.1819569116>, with PNAS permission.

(length/width) of pathogen bacteria and also demonstrated the performed microfluidic system to determine the AST in the positive samples. The adaptable platform was capable to detect bacterial pathogenic in several biological fluids such as urine, whole and culture blood and analyzing polymicrobial samples.

Droplet microfluidics

Droplet microfluidics is a promising system rapidly emerging as a new approach for studies and applied with success in diagnostic microbiology such as identification of pathogens, studies of microbial physiology and antimicrobial resistance (Kaminski et al., 2016). By using microfluidic droplet, the microbial culturing is carried out in bioreactors, and then the individual bacteria separate

using stochastic confinement in tiny pico to nanoliters volume with bacteria cells, medium and reagents well-defined for analytical assay (Keays et al., 2016), evaluated Droplet created as bioreactors to test the growth of *E. coli* treated by ampicillin and kanamycin. The result demonstrated the performance of Droplet to determined resistance of strains for antibiotic agents within 1 h. The application of droplet microfluidics for studying the antibiotic susceptibility testing were presented in several recent reviews (Hassan and Zhang, 2014; Kaminski et al., 2016; Ortseifen et al., 2020; Qin et al., 2020; Zhang et al., 2020). The droplet microfluidics presented several advantage such as the confinement of the reaction in small volume, high throughput analysis and sensitive assays, small volume load and flexible manipulation and detection. The Droplet eliminates the risk of contamination, minimize fouling and generate large number of bioreactor for single bacterial analysis (Guo et al., 2012; Zhang et al., 2020). For screening antibiotics/pathogens simultaneously (Kang et al., 2019), developed highly-throughput droplet microfluidic AST platform for testing Gram positive and negative bacteria. The system developed is rapid sensitivity response within 15–30 min compared to standard methods (16–24 h), could be used as an excellent alternative to standard AST methods in clinical diagnostics to screen several antimicrobial agents (Miller et al., 2012) described a robust droplets-based microfluidic platforms high-resolution and rapidly generate high-quality dose-response data during drug screening. The droplet microfluidic platform for high-resolution is rapidly generating dose-response curves drug screening, with large number of dose-response containing approximately 10,000 data points per compound for small molecule. For rapid toxicity screening of mixture antibiotics, an another automated droplet-based microfluidic system was used by Churski et al. (2012). By using the microfluidic system developed in this study, the MICs of ampicillin, chloramphenicol and tetracycline were determined for *E. coli*. After then, a rapid MICs values were evaluated, and the different types of interactions of *E. coli* were determined.

Molecular methods for antibiotic resistance detection

Amplification-based methods

Conventional polymerase chain reaction (PCR)

PCR is a molecular technique acquiring greatest value in diagnostic in clinical microbiology by allowing both a precisely identification of pathogenic microorganisms, detection of resistance genes and virulent genotypes (March-Rosselló, 2017). PCR was developed by Kary Mullis (Saiki et al., 1989), permitting rapid and exponential amplification of target DNA sequences using a forward and reverse PCR primers and DNA polymerase enzyme. Conventional PCR consists of successive reaction cycles. In each one the number of targeted extracted DNA molecules is doubled, allowing the exponential number increase of targeted DNA molecules. The cycle is including three steps: (a) denaturing of the double stranded DNA at 95 °C, (b) annealing of the PCR primers at 50–60 °C, and (c) extension of the DNA at 72 °C. Through electrophoresis or other molecular techniques, the amplified target could be confirmed for the existence of resistance genes (Khan et al., 2019). The whole process, including DNA extraction, amplification and visualization, requires 12 h (March-Rosselló, 2017).

PCR using for detecting AMR gene's presence in pure cultures of bacteria or even in polymicrobial samples is currently ordinary. Numerous PCRs was successfully used for both aerobes and anaerobes bacterial strains due to the ease of designing conventional PCR primers (Anjum et al., 2018). List of primers to detect AMR genes is available at the website of the European Reference Laboratory for Antimicrobial Resistance (EURL AMR) (http://www.eurl-ar.eu/data/images/faq/primerliste%20til%20web_07.11.2013.pdf).

Real-time PCR (RT-PCR)

RT-PCR was designed to shorten the time compared to conventional PCR and can detect single point mutations in a given gene if sequence-specific DNA probes targeting the mutation area are used (March-Rosselló, 2017). RT-PCR was used in rapid detection of antibiotic resistance in *mecA* methicillin resistance gene associated MRSA pure isolate, specimens or in staphylococci mixtures (Huletsky et al., 2004; Tenover, 2009; Liu et al., 2016a,b). The multiplex real-time PCR assay was proposed by Kim et al. (2013), to be used in regions of high endemicity for methicillin-resistant *S. aureus* (MRSA) infections. This assay detected simultaneously the *mecA*, staphylococcal cassette chromosome (SCC*mec*)-open reading frame X (*orfX*) junction, and staphylococcal 16S rRNA genes to avoid false-positive results which may occurred by using a single-locus real-time PCR assay.

The accuracy of real-time PCR for the detection of *Enterococcus* spp. (VRE) carrying vancomycin-resistant genes *vanA*, *vanB*, and *vanM* was proven in several investigations. The detection was achieved for pure isolates and directly in rectal swabs of colonized patients (Tenover, 2009; Cantarelli et al., 2011; He et al., 2020a,b,c). Direct detection of *M. tuberculosis* resistance mutations, in clinical respiratory samples, was conducted by Real-time PCR. The technique has minimized the time required to obtain the susceptibility pattern of strains and the mutation encoding resistance to Rifampin and Isoniazid was effectively detected in all sputa harboring resistant *M. tuberculosis* strains (Marín et al., 2004). The use of real-time PCR assays to quantify the abundance of tetracycline (*tet*) resistance in agricultural environments was reported. This assay was proposed to be useful for antibiotic resistance ecological studies (Yu et al., 2005).

Loop-mediated isothermal amplification (LAMP)

LAMP tool developed by Notomi (2000) on the basis of PCR has moreover been used for AMR detection. In LAMP, the target gene is amplified at a constant temperature of 60–65 °C using a *Bst* DNA polymerase as a substitute of *Taq* polymerase (Li et al., 2017)

because of strong strand displacement activity (Khan et al., 2019). This method is expected to amplify the target sequence with high selectivity by an employs of a polymerase and a set of four specially designed primers that recognize a total of six distinct sequences on the target DNA (Notomi, 2000).

In the last two decades, many investigations report that due to the simplicity and rapidity of the LAMP assay (conventional, multiplex or coupled to other methods) its use can be very practical in clinical microbiology laboratories. The LAMP based essay offers numerous clinical possibilities for use as an alternative tool for the rapid detection of resistance genes. Moreover, LAMP can help in facilitating epidemiological studies and permitting enhanced monitoring of the emergence of drug resistant strains (Mu et al., 2016). Among LAMP-based system the eazyplexw SuperBug CRE proved to be a potent tool for the detection of various carbapenemases as well as CTX-M-type ESBLs in *Enterobacteriaceae* with a rapid resolution time. The system detected perfectly *bla* carbapenemase genes with or without *bla*CTX-M genes in 100% of the molecular characterized strains of *Enterobacter cloacae*, *Klebsiella pneumoniae*, *K. oxytoca*, *E. aerogenes*, *Citrobacter freundii*, *E. coli*, *Raoultella ornithinolytica*, and *Kluyvera ascorbata* (Garcia-Fernandez et al., 2014). LAMP assay was used by Mu et al. (2016) for detection of IS*Aba1*-*bla*_{OXA-51-like} carbapenem-resistance gene in *A. baumannii* isolated from clinical settings. The work reveals that this method showed great potential in detection of AMR genes directly from clinical specimens and has demonstrated 100-fold more sensitivity than the PCR method. Recently, Baek et al. (2020) developed a simple and rapid method for detecting vancomycin resistance genes, such as *vanA* and *vanB*, by using LAMP. Compared to RT-PCR, the sensitivities and specificities of LAMP was 100/100% for both 16S rRNA, *vanA*, and *vanB*.

Restriction endonuclease-based multiplex loop-mediated isothermal amplification (multi-LAMP) assay was established by Zhong et al. (2019) to detect *mcr* genes (*mcr*-1 to *mcr*-5) harbored by colistin-resistant Gram negative bacteria. The method sensitivity was 10-fold greater than that PCR. Multi-LAMP assay can help to prevent infections by drug resistant bacteria in primary-care hospitals. Multiplex loop-mediated isothermal amplification linked to a nanoparticle-based lateral flow biosensor (m-LAMP-LFB) is a novel molecular diagnosis technique established by Chen et al. (2020) to detect *S. aureus* species and identify MSSA and MRSA from clinical samples (Fig. 6). By designing primers based on the *femA* gene (*S. aureus*-specific gene) and the *mecA* gene (encoding penicillin-binding protein 2a) the detection was 100%, allowing that m-LAMP-LFB is a consistent, simple, rapid, specific and sensitive method to identify MSSA and MRSA infections for suitable antibiotic treatment.

Recombinase polymerase amplification (RPA)

The approach of DNA detection by using RPA was designed by Piepenburg et al. (2006). RPA couples isothermal recombinase-driven primer targeting of template material with strand-displacement DNA synthesis. An exponential amplification is achieved with no pretreatment of DNA sample. The technology is sensitive to less than 10 copies of genomic DNA.

The use of RPA to detect the antimicrobial resistance gene were described by Nelson et al. (2019) as an excellent approach for genomic antimicrobial resistance testing in clinical settings and for point-of-care application. The RPA method showed to be rapid, cost-effective tool for antibiotic resistance surveillance for both pathogens and commensals, without nucleic acid purification. In their investigation, the detection of macrolide efflux gene *A*, *mef(A)*, provides resistance against erythromycin and azithromycin was achieved by using RPA tool. The *mef(A)* detection was conducted in raw lysates of *Str. pyogenes*, *Str. pneumoniae*, *Str. salivarius*, and *E. faecium* within 7–10 min of assay time (Nelson et al., 2019).

Hybridization-based methods

The DNA analysis to detect particular mutations or polymorphisms can be accomplished by differential hybridization with sequence-specific oligonucleotide probes. Several hybridizations-based methods are used for detecting AMR mutation in DNA elements of bacterial species.

Array-based methods

DNA microarrays and DNA chips technologies are promising used for assessing antimicrobial susceptibility and even detecting antimicrobial resistance (Frye et al., 2010). The DNA microarray is based on using an image analysis to detect hybridization of a target molecule to a specific probe immobilized on a solid base (March-Rosselló, 2017). Initially, specific probes of each gene are deposited onto a solid substrate (generally glass) in a lattice pattern. Then the DNA is labeled and hybridized to the array, and the specific target-probe duplexes are detected with a reference molecule (Schna, 2000). The presence or absence of genes in the test isolate, in comparison to a reference, was determined by analyzing the hybridization results (Anjum et al., 2018). In a single Microarrays assay a large number of resistance genes can be detected given that these probes are attached very close to one another (March-Rosselló, 2017). Indeed, simultaneous detection of 91 resistance determinants in *A. baumannii* was achieved by using DNA microarray validated with 60 multidrug-resistant *A. baumannii* strains, within 4 h from bacterial culture to result (Dally et al., 2013). Mutation point detection has been carried effectively through DNA microarrays system assessment of *M. tuberculosis* clinical isolates (Fig. 7) in the work conducted by Huang et al. (2014). Predominant mutations in the *rpoB*, *katG* and *inhA* genes have been detected in clinical isolates of *M. tuberculosis*. Among 324 strains of tested *M. tuberculosis*, 210 were detected as MDR. Detection of rifampicin and isoniazid mono-resistance was reported for 41 and 34 isolates, respectively, while none resistance was detected in 39 isolates

Fig. 7 (A) Layout of probes on the array (a) position marker, (b) positive control, (c) internal amplification control and (d) wild-type probe. (B) Three multidrug-resistant *Mycobacterium tuberculosis* isolates (a–c) and one isoniazid (INH) mono-resistant isolate (d) were analyzed with the array. Reprinted and modified from Huang WL et al. (2014) Rapid and accurate detection of rifampin and isoniazid-resistant *Mycobacterium tuberculosis* using an oligonucleotide array. *Clinical Microbiology and Infection* 20(9): 0542–0549. <https://doi.org/10.1111/1469-0691.12517>, Copyright © 2014, with permission from Elsevier.

(Huang et al., 2014). Moreover, array-based method was largely and successfully employed in the rapidly and accurately AMR gene detection in numerous bacterial species, including MDR *S. enterica* serovars, *E. coli*, *Campylobacter* spp., *Enterococcus* spp., methicillin-resistant *S. aureus*, *Listeria* spp., *Clostridium difficile*, *A. baumannii* and drug-resistant *M. tuberculosis* (Frye et al., 2010; Dally et al., 2013; Huang et al., 2014).

Lab-on-chip methods

Several approaches of Lab-on-a-chip (LoC) devices using microfluidics provided rapid detection of AMR (Kaprou et al., 2021). In genotypic microfluidic assays-PCR or LAMP based, the integration of nucleic acids detection in the device represents a highly promising approach (Giuffrida and Spoto, 2017). For targeting genetic markers of AMR genes in pathogenic bacteria implicated in post-neurosurgical meningitis (Zhang et al., 2018) developed a novel, fast, accurate and easy-to-use micro/nanofluidic chip platform. The method can identify 10 genus or species targets (108 bacterium) and 13 genetic resistance determinants within 1 h: carbapenemase, extended-spectrum beta-lactamase (ESBL), *mecA* and *vanA*, *vanB* related antibiotic resistance genes.

A Lab-on-a-Film disposable (Fig. 8) for rapid detection of multi-drug resistant *M. tuberculosis* (MDR-TB) from sputum extracts was constructed by Kukhtin et al. (2019, 2020). Gel elements (203) printed on including DNA sequences (probes) for 37 genetic mutations, deletions, or insertion elements through five genes were employed in the designed disposal. In order to form a microfluidic flow cell, gel elements are printed on a flexible film, which is next laminated to additional rollable materials (films). Consequently, in a single microfluidic chamber are combined, multiplex amplification, hybridization, washing and array imaging steps. The closed format of the Lab-on-a-Film Assembly (LFA) avoid amplicon contamination.

Line probe assays (LPAs)

In a conventional assay with immobilized PCR product and labeled oligonucleotide probes, each probe requires separate hybridization. This approach is reversed in LPA and uses reverse hybridization (Fig. 9). Thus, a large number of wild type and mutant sites are interrogated and differentiated by analysis of several entire sequences simultaneously in a single hybridization reaction (Saiki et al., 1989; Marinus Barnard et al., 2012). A biotin tag is added to each sample DNA sequence previously extracted from a clinical sample and amplified. The amplified DNA is denatured and single stranded DNA probes for resistance genes are attached to a band. The sequences of probes are attached to a strip if they are complementary to it with a known location. The unbound DNA sample is washed with alkaline phosphatase. A streptavidin anchor is added to the strip, which binds to DNA sequences labeled with biotin. Nitro blue tetrazolium (NBT) and 5-bromo-4-chloro-3-indolyl-phosphate (BCIP) are added. They cleave alkaline phosphatase, turning it into a dark blue dye, on which the sample DNA has bound (Saiki et al., 1989; World Health Organization (WHO), 2000).

Development of LPAs assays to detect mutation genes such as *gyrA* mutations, *inhA* and *katG* mutations, *rpoB* gene and *katG* gene mutations conferring resistance to fluoroquinolones, rifampicin and isoniazid in *M. tuberculosis* shown the effectiveness of this approach (Giannoni et al., 2005; Farooqi et al., 2012; Kazemian et al., 2019). Moreover, LPAs demonstrated high accuracy generally for the detection of rifampicin resistance and high specificity for isoniazid resistance detection (Nathavitharana et al., 2017).

Fluorescence in situ hybridization (FISH)

In situ hybridization (ISH) was developed by carrying out hybridization of Radiolabeled DNA to cytological preparations from *Xenopus oocytes* without altering their cell morphology or integrity (Call et Pardue, 1969; John et al., 1969). The formed molecular hybrids radiolabeled probes- DNA were detected by autoradiography. Radioactive labels were progressively replaced by nonisotopic dyes (Landegent et al., 1984; Pinkel et al., 1986, 1988), hence FISH using fluorescent labels were used for detection of microbial single cells (DeLong et al., 1999). FISH can be used for the diagnosis of infectious diseases in case of blood-culture-negative endocarditis, respiratory infections, gastrointestinal diseases, mycobacterial infections, highly pathogenic microorganisms and other fastidious bacteria such as spirochetes (Prudent and Raoult, 2019). The procedure includes the following steps: (i) fixation of the studied microorganism cells or tissues; (ii) specimens pretreatment and permeabilization step, to achieve the access of the probes to the nucleic acids; (iii) hybridization of short fluorescent labeled single-stranded oligonucleotide probes to ribosomal RNA (rRNA) of the target microorganism; (iv) washing steps to eliminate unbound probes; (v) mounting and imaging by microscopy or flow cytometry and documentation of results (Möter and Göbel, 2000).

The simultaneous detection of one or multiple targets providing resistance made FISH a suitable tool for detection antimicrobial resistance determinants especially for ribosomally mediated ones. Such resistance in which antibiotic drugs like macrolide or linezolid are affected, allowed intense fluorescence signals because ribosomal RNA copies are numerous in living cells (Frickmann et al., 2014). Detection of linezolid enterococci resistance was achieved by FISH essay by detecting a single mutated 23S rRNA gene allele in phenotypically linezolid-susceptible *E. faecium* (Werner et al., 2007). Peptide nucleic acid-fluorescence in situ hybridization

Fig. 10 Detection of TEM β -lactamase mRNAs and the respective protein in *E. coli*. (A) FISH staining of TEM β -lactamase mRNA in *E. coli* harboring pLitmus38 (red) and the ribosomal RNAs by Enterobac (green). (B) Antibody (green) and DNA/DAPI (blue) staining of the TEM β -lactamases in *E. coli* harboring pLitmus38 (left) or pUC18 plasmids (right). Reprinted from Rohde A, Hammerl JA and Al Dahouk S (2016) Rapid screening for antibiotic resistance elements on the RNA transcript, protein and enzymatic activity level. *Annals of Clinical Microbiology and Antimicrobials* 15(1): 55. <https://doi.org/10.1186/s12941-016-0167-8>, under a Creative Commons Attribution 4.0 International License (CC BY).

(PNA-FISH) appear to be a simple, quick, and accurate method for detecting *H. pylori* clarithromycin resistance. The method showed high sensitivity and specificity for the patients harboring clarithromycin-resistant *H. pylori*, which could improve the patient's chances of a more effective *H. pylori* eradication. The method demonstrated to be able to discriminate susceptible and resistant *H. pylori* genotypes on gastric biopsy specimens (Cerqueira et al., 2013). Rohde et al. (2016) used plasmid-encoded TEM β -lactamase conferring ampicillin resistances to develop a FISH -test able to detect the respective mRNAs (Fig. 10). FISH assay demonstrated to be sensitive to detect signals in all *E. coli* TEM β -lactamase producing strains harboring pLitmus38 and pUC18 plasmids (Rohde et al., 2016).

A methylation-sensitive RNA fluorescence in situ hybridization was developed by Ranasinghe et al. (2018) to detect methylated bases in tRNA, rRNA and mRNA, which control several cellular processes, including antimicrobial resistance. Detection of single methylations of rRNA, quantifies antibiotic-resistant bacteria in cells mixtures and detects multiple methylations by using multi-color fluorescence imaging (Ranasinghe et al., 2018). Recently, the development of novel nanoprobe for FISH and the application of the nanoprobe to the detection of ampicillin-resistant *E. coli* was reported. F-nanoprobe and R-nanoprobe were prepared for the discrimination of *rrnB* and *bla* genes in *E. coli*, respectively. By using R-nanoprobe-*bla* for antimicrobial resistance identification detection of beta-lactamase sequence of ampicillin-resistant *E. coli* was possible by microscopic observation (Lee et al., 2019).

Immunoassays, to detect AMR gene: Lateral flow assays LFAs

Lateral flow assays (LFAs) technique is based on biochemical reaction of antigen-antibody or probe DNA-target DNA hybridization. Four parts constitute the lateral flow test (LFA): (i) a sample pad: the sample is placed on this area; (ii) conjugate pad: compartment where labeled tags are combined with biorecognition elements; (iii) reaction membrane: comprises the test line and the control line; an absorbent pad: used to accumulate waste. In order to increase the sensitivity of assays gold nanoparticles, colored latex beads, carbon nanoparticles, quantum dots, and enzymes are used as labels (Bahadır and Sezgentürk, 2016). Immunoassay methods implicate the direct detection resistance markers protein which are captured and enriched by using antibodies. Antibodies or resistance proteins can be labeled with fluorescent tags for visualization and their interaction requires optimization (van Belkum et al., 2020). Several investigations developed products for the direct detection of antibiotic resistance proteins targeting specific protein markers of resistance. Fig. 11 illustrate the immunochromatography using mAbs 1E2-7 and 4E4-4 that reacted with recombinant NDM-1 type metallo- β -lactamase produced by *K. pneumoniae*.

Specific immunochromatographic assay using the aminoglycoside-modifying enzyme 6'-N-acetyltransferase-Ib [AAC(6')-Ib], aminoglycoside 6-N acetyltransferase (AAC(6')-Iae) and IMP-type metallo- β -lactamases as molecular markers designed to detect respectively MDR *P. aeruginosa* and carbapenem resistance in *Pseudomonas* (Kitao et al., 2010; Tada et al., 2011, 2016). Carbapenem resistance in Gram negative bacilli was accurately detected by development of LFAs producing immunochromatographic cross-reaction with NDM (New Delhi metallo- β -lactamase), OXA-23 (carbapenem-hydrolyzing oxacillinase); OXA-48 (oxacillinase-like), OXA-163 subfamilies, KPC (*K. pneumoniae* carbapenemase), and VIM (verona integron-encoded metallo- β -lactamase) carbapenemase (Pasteran et al., 2016; Boutal et al., 2017; Mertins et al., 2019; Rösner et al., 2019; Tada et al., 2019). LFA was described as a tool for the rapid detection and monitoring of MCR-1 *Enterobacteriaceae* producers harboring plasmid encoded colistin resistance gene *mcr-1* causing resistance to polymyxin, the last-resort antibiotic for the treatment of infections caused by highly drug-resistant Gram-negative bacteria (Volland et al., 2019). Multiples studies involved the development and optimization of lateral-flow assay for the detection of the penicillin-binding protein 2a (PBP2a) in methicillin resistant *S. aureus* (MRSA). The detection process takes between 15 and 20 min and does not necessitate special tools (Yamada et al., 2013; Amini et al., 2020). Recently, the establishment of an LFA assay for MRSA detection on the basis of the ability of an aqueous soluble cellular wall-binding domain (CWBD) protein from bacteriophage P108 to act as a wide-spectrum binding agent for all MRSA strains was conducted. The LFA was designed in sandwich format: the signal probes for tracing MRSA used is CWBD-coupled time-resolved fluorescent microspheres (FMs); MRSA capture was carried out by nitrocellulose membrane immobilized with porcine IgG (Fig. 12). The MRSA detection could be achieved within 10 min at cells concentration range of 6.6×10^2 – 6.6×10^7 CFU mL⁻¹. LFA strip using recombinant CWBD as the recognition agent may be a

promising approach for POC testing of MRSA (Yang et al., 2021). For vancomycin-resistant enterococci *VanA* and *VanB*-producing rapid detection a LFIA assay (called NG-Test *VanA* and NG-Test *VanB*) was constructed Oueslati et al. (2020, 2021). Detection of VRE was possible from both cultured colonies and blood samples.

Whole genome sequencing (WGS)

WGS is used to obtain the complete DNA sequence of a microorganism. A comparison between a DNA sequence and standard reference sequences, deduction may provide information about important phenotypic traits of the microorganism, such as AMR (World Health Organization (WHO), 2019). WGS is situated to become an essential tool in the control of antibiotic resistance due to recent improvements in sequencing technologies providing fairly long reads at high speed, such as Illumina MiniSeq, Pacific Biosciences PacBio Sequel system, or Oxford Nanopore MiniON and PromethION can (Köser et al., 2014; Vasala et al., 2020). More than 40 freely accessible Bioinformatics tools for detection of AMR determinants in DNA or amino acid sequence data have been developed, including ARG-ANNOT, CARD Comprehensive Antibiotic Resistance Database, SRST2, MEGARes, Genefinder, ARIBA, KmerResistance, AMRfinder, and ResFinder (Hendriksen et al., 2019). The WGS is used in numerous applications in medicine such as the development of new antibiotic and rapid identification of resistance mechanisms, the surveillance and control of infectious diseases and detection of antibiotic resistance in the clinical microbiology (Köser et al., 2014).

Introduction

There is a growing interest in the use of microorganisms as a source of secondary metabolites. Microbes are skilled producers of valuable natural products which exhibit a plethora of biological activities such as antibiotics, anticancer, antiviral, antileishmanial, and anthelmintic (Demain, 2014; Pham et al., 2019; Cruz et al., 2021), as well as biotechnological processes in sustainable agriculture and food industry (Adrio and Demain, 2014).

The continuous and sometimes uncontrolled use of antibiotics contributes to the spread of resistance. Among this, several developed and approved natural products or derivatives are based on old discoveries and, since the 1960s, no new class of broad-spectrum compounds has been discovered (Fischbach and Walsh 2009; Lewis, 2013; Walsh and Wencewicz, 2014; Ling et al., 2015; Sabino et al., 2019; Cruz et al., 2020). Deaths caused by drug-resistant bacteria overpass 700,000 cases every year worldwide (Bos and Austin, 2018). Such pathogens are capable to prevail to antibiotics through mechanisms regulated by antibiotic-resistance encoding genes which can (A) change the permeability of bacterial cell wall or active efflux which restrict the antimicrobial access to target sites, (B) modulation or degradation of the antibiotic by enzymatic activity, and (C) acquisition of alternative metabolic pathways or modification of active antibiotic sites (van Hoek et al., 2011) (Fig. 1). According to the Centers for

Fig. 1 Bacterial resistance timeline. Between 1962 and 2000 no new classes and/or effective antibiotics have been discovered. Additionally, resistant pathogens are rapidly spreading whereas the discovery of novel substances and their application to clinical practice is not fast enough. Adapted from Fischbach MA and Walsh CT (2009) Antibiotics for emerging pathogens. *Science* 325(5944): 1089–1093, doi:10.1126/science.1176667; Lewis K (2013) Platforms for antibiotic discovery. *Nature Reviews. Drug Discovery* 12(5): 371–387, doi:10.1038/nrd3975; Walsh CT and Wencewicz TA (2014) Prospects for new antibiotics: A molecule-centered perspective. *The Journal of Antibiotics* 67(1): 7–22, doi:10.1038/ja.2013.49.

Disease Control and Prevention (CDC), “superbugs” which belong to the ESKAPE group are the major nosocomial opportunistic pathogens. Methicillin-resistant *Staphylococcus aureus* (MRSA) is omnipresent in hospital environment which can overpass 50% of antibiotic resistance rates in 5 out of 6 world regions, whereas the Gram-negative *Acinetobacter baumannii* is a biofilm-forming deadly pathogen which exhibits mortality rates as high as 60% (Park et al., 2016; Chen et al., 2018; Lee et al., 2018; Turner et al., 2019) (Fig. 1). Consequently, the need to explore niches that house microorganisms that could produce bioactive metabolites are critical.

Likewise, infectious diseases caused by phytopathogenic fungi can affect harshly several crops worldwide. Additionally, conventional agriculture practices are not ecologically safe since that the use of agrochemicals is famous for the harm to the environment and human health. On the other hand, beneficial microbes represent a sustainable alternative to negative repercussions caused by these agents. Microorganisms are capable to inhibit or suppress plant pathogens and influence directly and indirectly plant growth by the solubilization of important substances such as phosphate or by the biosynthesis of phytohormones, siderophores, and enzymes (Cullen et al., 2019; Omomowo and Babalola, 2019; White et al., 2019).

Neglected diseases still are a burden in low-income tropical and subtropical communities (Molyneux et al., 2017). Leishmaniasis are transmitted by more than 20 species of *Leishmania* protozoan and are classified as Neglected tropical diseases (NTDs), a diverse group of communicable diseases that prevail in tropical and subtropical conditions in 149 countries, affecting more than a billion people and cost developing economies billions of dollars every year (Alcántara et al., 2018; Bekhit et al., 2018; Moreira et al., 2020; Santos et al., 2020). Moreover, it is important to mention that the current therapies of leishmaniasis exhibit significant recurrence rates, and pentavalent antimonials-based treatment is known to be unsafe and ineffective as well therapies based on the administration of pentamidine and Amphotericin B are considered toxic (Lindoso et al., 2012; Toghueo, 2019).

In addition, cancer continues to be a major cause of morbidity and mortality in millions of people worldwide, devastating the public health system (Rayan et al., 2017; Wali et al., 2019; Sharifi-Rad et al., 2019). Therefore, the possibility to introduce new substances from natural sources that can effectively tackle infectious diseases, malignancies, and biofertilizers might promote an increase in longevity and minimize the negative impacts on health and the environment.

Herein, we address a review topic concerning the main tools and protocols for isolation and characterization of these microbe-producing drugs.

Medicines and microbe sources

Microorganisms are capable to produce a wide variety of secondary metabolites, also known as natural products. This diverse group of agents is the foundation of the development of various biopharmaceutical, agrochemicals, and biotechnological products (Pham et al., 2019). The discovery of penicillin in 1928 by Alexander Fleming is considered an important milestone that revolutionized the search for medicines since that in the early 1900s almost 80% of all medicines were derived from plants (Lobanovska and Pilla, 2017; Pham et al., 2019).

Potential candidates might be found in several niches, such as soil, *epi*/endophytically associated with plants, animals, and marine habitats (Giddings and Newman, 2013; Pham et al., 2019). However, nearly 99% of all species of external environments are promising and unculturable (Ling et al., 2015). Ling et al. (2015) reported the discovery of the potent antibiotic compound teixobactin against Gram-positive and drug-resistant pathogens. This substance is produced by the non-cultivable *Eleftheria terrae*, isolated from soil using the device known as the iChip. It is known that bacterial resistance to antibiotics is a worldwide life-threatening concern (Aslam et al., 2018; Peterson and Kaur, 2018). However, teixobactin exhibits properties that minimize the generation of *S. aureus* and *Mycobacterium tuberculosis* mutants.

Soil is an extremely diversified niche, where microorganisms compete to survive. Therefore, microbes' secondary metabolism is influenced by other microorganisms to control them (Onaka, 2017). Actinobacteria is presented in 10–50% of the soil microbial community. These Gram-positive filamentous spore-forming bacteria are characterized by their large linear chromosomes exhibiting high GC content (Amin et al., 2020; Lee et al., 2020; Prudence et al., 2020; van Bergeijk et al., 2020). Despite being a significant percentage of soil microbiota, it was reported the isolation of actinomycetes from other sources, including insect-associated *Streptomyces* spp. (Chevrette et al., 2019; Olanrewaju and Babalola, 2019). In terms of the diversity of secondary metabolites, members of *Streptomyces* genus are skilled producers of a wide variety of bioactive substances economically important (Genilloud, 2018). Approximately, more than 80% of the antibiotics industrially produced are obtained from these actinobacteria (Grasso et al., 2016; Cruz et al., 2020).

Streptomycin, cephalosporin, chloramphenicol, and tetracycline are antibiotics originally isolated from *Streptomyces* species (Procópio et al., 2012), as well approximately 55% of all this class of medicines discovered between 1945 and 1978 are related to *Streptomyces* genus (Hutchings et al., 2019).

Interestingly, Streptomyces when intimal interaction with mycolic acid-containing bacteria (*Mycobacterium* spp., *Rhodococcus* spp., *Dietzia* spp., *Nocardia* spp., *Williamsia* spp., *Gordonia* spp., *Corynebacterium* spp., and *Tsukamurella* spp.) are capable to activate their cryptic metabolism (Onaka et al., 2011; Hoshino et al., 2019). Cryptic genes are silent biosynthetic gene clusters that are not expressed during the microbial life cycle or in usual laboratory conditions (Tamburini and Mastromei, 2000). Onaka et al. (2011) reported the discovery of the antibiotic alchivemycin A and the production of a red pigment which were obtained from the co-cultivation of *Streptomyces endus* S-522 and *Tsukamurella pulmonis* TP-B0596 and *S. lividans* TK23 and *T. pulmonis*, respectively. Alchivemycin A is a versatile polycyclic polyketide that possesses an antimicrobial profile against *Micrococcus luteus* and is capable to

inhibits the invasion of murine colon carcinoma without showing cytotoxic effects (Kim et al., 2013). Combined cultures might modulate the cryptic secondary metabolism in 90% of *Streptomyces* species when compared to axenic cultures (Onaka, 2017; Caraballo-Rodríguez et al., 2017; Chagas and Pupo, 2018), and since the discovery of alchivemycins, this approach has been reported in several studies (Hoshino et al., 2015a, b; Sugiyama et al., 2015).

Actinorhodin was first reported by Brockmann and Pini (1947). This polyketide is a blue-pigmented antibiotic (in its basic pH, whereas is red at acidic pH) which inhibits the growth of Gram-positive bacteria, originally produced by *Streptomyces coelicolor* (Xu et al., 2012; Mak and Nodwell, 2017; Nass et al., 2017). *S. coelicolor* is considered a model organism and is known that its genome exhibits more than 20 biosynthetic gene clusters (Chater, 2016; Bobek et al., 2017; Čihák et al., 2017).

Biotechnologically, the *Streptomyces* genus occupies a prominent position. However, within the *Actinobacteria* phylum, other genera such as *Micromonospora* and *Actinomadura* are important natural product bio-factories (Igarashi et al., 2012). Both are skilled in producing polyketides, an important class of bioactive compounds isolated from a wide species of microorganisms that might exhibit a plethora of biological activities (Wang et al., 2020). In Igarashi et al. (2012), the polyketide nomimicin, an inhibitor of *Micrococcus luteus*, *Candida albicans*, and *Kluyveromyces fragilis* was reported for the first time. This compound was obtained from the compost-isolate *Actinomadura* sp. TP-A0878.

On the other hand, microorganisms that live in the rhizosphere have gained substantial attention as a source of versatile bioactive natural products (Iniyan et al., 2017; Zhang et al., 2019). The rhizospheric space (Fig. 2) comprises a narrow soil zone that surrounds plant roots. This complex and dynamic region harbors a rich microbiota that is attracted by nutrients, exudates, border cells, and mucilage released nearby plant roots (Philippot et al., 2013; Cruz et al., 2020).

The quorum communication of rhizospheric microbial community (bacteria, fungi, arbuscular mycorrhizae, oomycetes, viruses, and archaeas) may directly or indirectly modulate plant's composition and its biomass by the biodisponibilization of phosphate in the soil, production of natural products (phytonutrients and antibiotics) that might influence its growth and stimulate plant's defense system (Godinho and Bhosle, 2013; Philippot et al., 2013; Lacava and de Sousa, 2016).

Aside from medical applications, the use of microorganisms can reduce the use of phosphate fertilizers and agrochemicals which affect directly human and environmental health.

Fig. 2 Representation of the micro-community that surrounds the rhizospheric space. The quorum communication might trigger microbes' secondary metabolism, which can influence positively plant growth or produce antibiotics and other substances that can protect the plant against stress conditions, including herbivory harm by pests and control of plant pathogens. Adapted from Philippot L, Raaijmakers JM, Lemanceau P, and van der Putten WH (2013) Going back to the roots: The microbial ecology of the rhizosphere. *Nature Reviews. Microbiology* 11(11): 789–799, doi:10.1038/nrmicro3109; Cruz FDPN, Bogas AC, and de Sousa CP (2020) Plant-associated microorganisms as a potent bio-factory of active molecules against multiresistant pathogens. Microbiology*, 18(10): 546–558, doi:10.1038/s41579-020-0379-y.

Plants and endophytes

Humankind has been based on medicinal plants for centuries (Giang and Otsuka, 2018; Gómez and Luiz, 2018; Anand et al., 2019) to feel better. However, in some cases exploring natural compounds from plants is not a sustainable approach. Paclitaxel (Taxol®) (Fig. 3.) is a chemotherapeutic agent found in barks, roots, and branches of the native tree from Pacific *Taxus brevifolia*. However, its slow growth and low yields of paclitaxel are severe obstacles. To yield 1 kg of paclitaxel, it required 10,000 kg of bark (Wani et al., 1971; Stierle et al., 1993; Isah, 2015).

Plant-associated microorganisms have gained notoriety for their ability to synthesize plant-derived compounds (Zhao et al., 2011; Gouda et al., 2016), as well as a wide-range action of bioactive natural products (Alvin et al., 2014; Fadiji and Babalola, 2020). These microbes are capable to live in intimate interaction with the host plant without causing any apparent disease symptoms. These microorganisms are known as endophytes (Abdel-Razek et al., 2020). Stierle et al. (1993), reported the discovery that the endophytic fungus *Taxomyces andreanae* is capable to produce the paclitaxel.

Endophytes represent a rich and successful source of bioactive natural products in medicine, pharmaceutical, and biotechnological applications (Alvin et al., 2014; Ek-Ramos et al., 2019). These microorganisms are capable to produce a vast quantity of bioactive substances which directly enhance plant growth by the synthesis of hormones, nitrogen fixation, and phosphate solubilization and indirectly by the inhibition of phytopathogens (Martinez-Klimova et al., 2017; Savi et al., 2019; Pacifico et al., 2019) and other compounds which originally believed to be produced only by their host plants (Strobel et al., 2004).

The search for drugs for the treatment of malignant diseases is a global challenge. Medicines originally obtained from plants that do not meet the requirement from the global market have been discovered from endophytic fungi. In 1966 Wall and co-workers discovered the antitumoral and antileukemic alkaloid camptothecin from extracts derived from the Chinese tree *Camptotheca acuminata* and *Nothapodytes foetida* (Wall et al., 1966; Li et al., 2006; Uzma et al., 2018). As well as taxol, Puri et al. (2005) discovered an endophytic fungus-producing camptothecin *Entrophospora infrequens* isolated from the inner bark of *N. foetida*. Likewise, podophyllotoxin was isolated for the first time from *Sinopodophyllum* plants (major natural source) but is widely found in *Diphylleia*, *Dysosma*, *Juniperus* plants. Podophyllotoxin exhibits cytotoxic and antiviral is widely used in the treatment of human papillomavirus (HPV) tumor lesions, leukemias, lung, and testicle malignancies. Currently, is known that podophyllotoxin is produced by several species of plant-derived fungi such as *Phialocephala fortinii*, isolated from *Podophyllum peltatum* (Imbert, 1998; Eyberger et al., 2006; Uzma et al., 2018), *Fusarium oxysporum* (Kour et al., 2007), *Trametes hirsute* (Puri et al., 2006), *Aspergillus fumigatus* (Kusari et al., 2009), and *Alternaria tenuissima* (Liang et al., 2016).

Beauvericin is a versatile cyclic hexadepsipeptide mycotoxin which exhibits potent insecticidal, antimicrobial, antiviral, and cytotoxic effects. Beauvericin is an emerging toxic compound presented worldwide in the contaminations of food and feeds. It was described for the first time by Hamill et al. (1969) which was isolated from the entomopathogenic fungus *Beauveria bassiana*.

Fig. 3 Chemical structure of taxol. Adapted from PubChem.

However, it is known that beauvericin is also produced by several species of *Fusarium* (Wang and Xu, 2012; Mallebrera et al., 2018; Bertero et al., 2020). Campos et al. (2015) describe an endophytic beauvericin-producing *Fusarium* sp. isolated from *Caesalpinia echinata* Lam. (Fabaceae), a native tree from Brazil. Beauvericin exhibited a potent effect on amastigote and trypomastigote forms of *Trypanosoma cruzi* (IC₅₀ 1.9 µg/mL).

However, NTDs which are prevalent and closely related to poverty worldwide have been ignored for decades. Nevertheless, more than one billion people in 149 countries suffer from NTDs (Weng et al., 2018). Concerning leishmaniasis' treatment options, modern medicine still counts on few and toxicity drugs (Roatt et al., 2020). Optimistically, this scenario is changing positively, and new studies regarding the discovery of antileishmanial compounds have been published.

The study of Moreira et al. (2020) investigated the inhibitory potential of crude extracts of fungal endophytes associated with *Avicennia nitida*, a mangrove tree against pathogenic bacteria, phytopathogenic fungi, and *Leishmania infantum chagasi*. The crude extract of *Diaporthe* sp. strain FS-94(4) have shown 90% cell death at 6 mg/mL, whereas moderate activity *Staphylococcus aureus* ATCC 6538, *Escherichia coli* ATCC 25922, and *Salmonella enterica* serotype Enteritidis ATCC 19196, exhibiting MIC₅₀ of 756, 767, and 949 µg/mL, respectively. Moreover, endophytic fungi from mangrove ecosystems have gained special attention due to their ability to modulate mangroves' adaptation to extreme environments, which suggests that these endophytes are skilled and promising natural products source (Sebastianes et al., 2017; Nicoletti et al., 2018).

Microbial lipases are versatile enzymes for their capacity to catalyze several reactions. These biomolecules are responsible to hydrolyze insoluble fats, oils, and esters of fatty acids (Singh et al., 2016; Patel et al., 2019). Alves et al. (2018) investigated the effects of fungal-derived lipases on dermatophyte fungi (*Malassezia* sp. and *Microsporum canis*) and *Leishmania amazonensis*. Interestingly, the study showed that the crude extracts of lipase-producing fungal endophytes *Emericella nidulans*, and *Dichotomophora portulacae* were more effective on promastigote forms of *L. amazonensis* (IC₅₀ 1.120 and 0.834 µg/mL, respectively), whereas *Vermisporium*-like and *Dichotomophora boerhaaviae* exhibited IC₅₀ of 1.388 and 1.151 µg/mL.

Silva et al. (2020a) evaluated the bactericidal, antiprotozoal, and cathepsin V inhibition activities of various extracts obtained by combined cultures of phytopathogenic fungi *Colletotrichum horii*, *C. gloeosporioides*, *Fusarium guttiforme*, *Pestalotiopsis diospyri*, *Phoma caricae-papayae*, and *Phytophthora palmivora*. Extracts 45 (co-cultivation of *F. guttiforme*, *P. diospyri*, *C. horii*, and *P. palmivora*) and 46 (co-cultivation of *F. guttiforme*, *P. diospyri*, *C. horii*, and *C. gloeosporioides*) (Silva et al., 2020b) exhibited potent antibacterial activity by fusaric and 9,10-dehydrofusaric acids, which were the majority compounds in these extracts.

The Brazilian Cerrado, also known as Tropical Savannah, covers about 2,000,000 km², which represents approximately 23% of the land surface of the country. In terms of area, it is exceeded by only the Amazonia forest. This biome is characterized by the immense diversity of medicinal plants which are widely used in folk medicine (Gottsberger and Gottsberger, 2009; dos Santos et al., 2020; Bogas et al., 2020). *Solanum lycocarpum* Saint Hill, also known as "lobeira" is a medicinal plant that exhibits anti-inflammatory properties (Ratti, 2009; Cruz et al., 2020; Bogas et al., 2020). Ratti et al. (2011) investigated the antibacterial effect of the crude extract of the endophyte *Streptomyces tubercidicus*. In this study, the fractionated extract showed strong antibiotic activity against *E. coli* and *S. aureus*. *S. tubercidicus* is a well-known producer of tubercidin, a potent and multi-active pyrrolopyrimidine that exhibits antimycobacterial, antiviral, antitumor, and kills *T. cruzi* by the inhibition of metabolic processes (Smulson and Suhadolnik, 1967; Kónya et al., 2008; Liu et al., 2018).

Serrano et al. (2012) reported the isolation of the *Paenibacillus polymyxa* strain RNC-D as endophyte from leaves of *Prunus* sp., a plant native to Brazilian tropical savannah. This study focused on the optimization of growth conditions for the production of bioactive substances, where its fermentation broth was primary screened and revealed significant inhibition of *E. coli* and *S. aureus* (Serrano, 2009). *P. polymyxa* is a Gram-positive bacillus naturally resident of soil capable to produce a plethora of secondary metabolites ranging from plant growth promoters to various antibiotics (polymyxin) (Neris et al., 2017; Jeong et al., 2019).

Observations on target plant for prospecting endophytes such as the absence of herbivores raise the possibility of an efficient chemical defense mechanism which is possibly promoted by endophytes (Piza et al., 2015). Thus, endophytes can be considered as alternative suppliers of characteristic phytochemical compounds and represent a vast unexplored reservoir of unique chemical structures (Elias et al., 2018).

Identification and characterization

Prior to bioinformatic and automated tools, microbes were grouped and identified based on their phenotypic characteristics such as the shape of single cells, morphology of the colony, as well physiological and biochemical profiles (Tshikhudo et al., 2013; Franco-Duarte et al., 2019). Streptomycetes exhibit unique cultural characteristics. Velvety and circular colonies which are usually gray on the front color and beige on the bottom become visible after 7 days of cultivation followed by the production of geosmin which is responsible for their wet earth odor (Ratti, 2009). However, conventional methods take few or up to a dozen days (e.g., molds) and the comparative analysis of phenotypic characteristics is not enough for proper identification (Franco-Duarte et al., 2019).

The development of tools and methods based on a molecular level and the ever-increasing deposit of DNA sequences in databases emerged in the late 20th century (Franco-Duarte et al., 2019). The 16S rRNA gene is widely used for the identification of bacterial species for decades (Johnson et al., 2019). The 16S small subunit ribosomal gene exhibits approximately 1500 bp in length and is an exclusive and highly conserved housekeeping gene within species of prokaryotes (Osman et al., 2018; Johnson et al., 2019; Peker et al., 2019). On the other hand, the identification of fungal taxa is performed by the sequencing of the internal transcribed spacer (ITS) cluster of rDNA. This ~600 bp region is located between the small subunit (SSU) rRNA gene (18S) and the large

Fig. 4 (A) The bacterial 16S rRNA gene is divided into nine regions, where the red regions, represented by V2 and V8 exhibit lower phylogenetic resolution, whereas the V4-V6 (green) is the major functional center of 16S which is located in a high conserved domain (690 hairpin) which is responsible for several chemical interactions with other biomolecules (e.g., bind to “790 loop” and the domain IV of the 16S rRNA and 23S rRNA respectively). (B) The fungal rDNA SSU and LSU regions offer less genetic variation in comparison to ITS and are adopted for phylogenetic studies of higher taxonomic levels, whereas the sequencing of LSU in combination with ITS is used for species characterization. Adapted from Taylor DL, Walters WA, Lennon NJ, Bochicchio J, Krohn A, Caporaso JG, and Pennanen T (2016) Accurate estimation of fungal diversity and abundance through improved lineage-specific primers optimized for Illumina amplicon sequencing. *Applied and Environmental Microbiology* 82(24): 7217–7226, doi:10.1128/AEM.02576-16; Yang B, Wang Y, and Qian PY (2016) Sensitivity and correlation of hypervariable regions in 16S rRNA genes in phylogenetic analysis. *BMC Bioinformatics* 17: 135, doi:10.1186/s12859-016-0992-y.

subunit (LSU) rRNA gene (28S) (positioned at 5'-end and 3', respectively) and separated (ITS1 and ITS2) by 5.8S rRNA gene (Schoch et al., 2012; Taylor et al., 2016; Raja et al., 2017; Badotti et al., 2018; Yang et al., 2018) (Fig. 4.).

Despite its wide role in bacterial systematics, taxonomical classification by 16S rRNA gene offers poor discriminatory resolution for some genera such as *Acinetobacter*, *Aeromonas*, *Bacillus*, *Burkholderia*, *Pseudomonas*, *Stenotrophomonas*, and several other genera (Janda and Abbott, 2007). In *Burkholderiales*, for example, identities of 16S rRNA and Recombinase A (*recA*) genes can reach 100% and 95%, respectively within *Burkholderia cepacia* complex (Bach et al., 2017) whereas the phylogenetic determination based on Calmodulin (*CmdA*) for *Aspergillus* and Beta tubulin (*BenA*) for *Penicillium* and *Talaromyces* are accepted as the secondary determination of species level (Yilmaz et al., 2014; Tsang et al., 2018; Rajeshkumar et al., 2019). Therefore, Multilocus Sequence Analysis (MLSA) and polyphasic taxonomy approaches which are based on the phylogenetic inferences using concatenated housekeeping genes enable the investigation of evolutionary characteristics and high resolution at the species level (Yilmaz et al., 2014; Zhu et al., 2020).

Laboratory techniques

Isolation of microorganisms naturally present in soil, rhizosphere, and plants

Material

Phosphate Buffered Saline (PBS)

Petri dishes containing Tryptic Soy Agar (TSA), International *Streptomyces* Project medium 2 agar (ISP2a), Potato Dextrose Agar (PDA), and ISP3 (Oatmeal) agar

70% ethanol solution

2% NaClO solution

Sterile distilled H₂O

Sterile 20% glycerol solution

Soil/rhizosphere samples - 10 g

Plant samples (roots, stems, leaves)

250 mL Erlenmeyer flasks

Drigalski loop

Sterile blades

Cryovials

Loop-full

28 °C shaking incubator

Media recipes

All media should be autoclaved at 121 °C for 20 to 45 min and cooled at 25 °C or stored at 4 °C before use.

TSA - recommended to bacterial isolation

Tryptic Soy Broth media: 30 g/L. However, it might be prepared alternatively using pancreatic digest of casein (15 g/L), papaic digest of soybean meal (5 g/L), sodium chloride (5 g/L), and bacteriological agar (15 g/L) in a final pH of 7.3 ± 0.2 . Supplement with Benomyl at 50 µg/mL (Araújo et al., 2014).

IPS2 - recommended to actinobacteria isolation

Malt extract (10 g/L), yeast extract (4 g/L), glucose (4 g/L), and bacteriological agar (20 g/L) in a final pH of 7.3 ± 0.2 (Shirling and Gottlieb, 1966).

PDA - recommended to fungi isolation

Potato infusion broth (boil 200 g/L of sliced and unpeeled potatoes for 30 min), glucose (20 g/L), and bacteriological agar (15 g/L). Adjust the pH to 6.0. Alternatively, the commercial Potato dextrose broth medium must be prepared at a concentration of 39 g/L. Supplement with tetracycline (50 µg/mL) (Araújo et al., 2014).

ISP3 - recommended to Streptomyces spore-forming isolation

Cook or steam Oatmeal (20 g/L) for 20 min followed by the addition of 1.0 mL/L of trace salts solution. Adjust the pH of 7.2 then sterilize (Shirling and Gottlieb, 1966).

Trace salts solution

FeSO₄ · 7H₂O: 1.0 g/L

MnCl₂ · 4H₂O: 1.0 g/L

ZnSO₄ · 7H₂O: 1.0 g/L

Distilled water

Experimental procedure

Samples of soil/rhizosphere (10 g) must be placed in individual Erlenmeyer flasks containing 90 mL of sterile PBS (NaCl: 8.0 g/L; KCl: 0.2 g/L; Na₂HPO₄: 1.44 g/L; KH₂PO₄: 0.24 g/L; pH: 7.4) and incubated for 2 h at 28 °C/180 rpm (Andreote et al., 2008; Cruz, 2018).

Concerning endophytes isolation, plant structures are submitted to superficial disinfection to eliminate the epiphytic population. This pretreatment is based on serial washes in 70% ethanol, 2% NaClO, 70% ethanol, and a double rinse in sterilized distilled H₂O, which times of exposure on baths vary according to plant characteristics (e.g., sample thickness). Plant structures are then ground and incubated in PBS as described above (Araújo et al., 2014). Subsequently, 100 µL of decimal dilutions are inoculated and spread with the aid of a Drigalski loop in the respective medium and incubated at the same conditions until microbe growth (Fig. 5).

Target isolates must be streaked and purified in their respective medium and preserved in 20% glycerol solution at –80 °C for bacteria (Araújo et al., 2014). Fungi stocks are maintained at room temperature in sterile water vials containing fungal mycelial disks (Araújo et al., 2014). Actinobacteria must be grown and sporulate in ISP3 agar for 7 days at 28 °C. A 2 mL of 20% glycerol should be added to the plates containing spores which should be collected using a loop-full and transferred to cryovials before stock at –80 °C (Shepherd et al., 2010; Park et al., 2016).

Expected results and characteristics

Considering actinomycetes as the most productive secondary metabolites producers, the expected morphological isolations can be seen in Fig. 5. According to studies (Ratti et al., 2011; Serrano et al., 2012; Lacava and de Sousa, 2016), these endophytes developed as colonies regarding the traits: color, form, elevation, margin, diameter, surface, opacity, and texture (Zinniel et al., 2002).

Antimicrobial activity screening

Overlay assay

Material

Brain heart infusion agar (BHIIa)

Brain heart infusion broth (BHIIb)

Appropriate solid medium for target isolate growth (e.g., nutrient agar, ISP2, TSA, and PDA)

Sterile 0.85% saline solution

Chloroform

Spectrophotometer

Incubator (28 °C and 37 °C)

Fig. 5 Promising host plants and environments may be found in high biodiversity areas, in which microbes develop different survival strategies. Coastal (A) and Mangrove (B) areas in Atlantic forest, Brazilian Tropical Savannah (C). Rhizospheric soil adhered to plant root (D). Diversity profile of rhizospheric microorganisms isolated from *Polygala paniculata* (E). Discrete inhibition produced by the endophyte during the isolation of the endophytic community (F). Purified endophytic (G, H, and I) and rhizospheric (J, K, and L) microbes isolated from *Polygala paniculata*.

Media recipes

Brain heart infusion medium

Dissolve 37 g of BHI in 1 L of distilled H₂O, mix well and sterilize at 121 °C for 15 min.

IPS2 agar

Malt extract (10 g/L), yeast extract (4 g/L), glucose (4 g/L), and bacteriological agar (20 g/L) in a final pH of 7.3 ± 0.2.

0.85% saline solution

Dissolve 0.85 g of NaCl in 100 mL of distilled H₂O. Autoclave 15 min at 121 °C and store at room temperature.

Experimental procedure

Overlay assay is widely used for antibacterial agents screening detection. This approach is relatively inexpensive and requires minimal resources. Several studies employed this consolidated method (Piza et al., 2015; Song et al., 2017; Hockett and Baltrus, 2017; Rojas-Rojas et al., 2018; Kurnianto et al., 2020).

Herein, we describe the slightly modified method reported in Piza et al. (2015). Target isolates are pre-inoculated and grown at 28 °C (for the bacterial isolates: TSA medium for 24–48 h, whereas actinomycetes in ISP2 for 7 days). After the reactivation, colonies are selected and diluted in 0.85% saline and then inoculated in the center of glass plates containing the respective solid medium according to the kind of microorganism and incubated at 28 °C for 3–7 days.

Pathogenic strains (e.g., *S. aureus*, *E. coli*, and *C. albicans*) must be overnight cultured in BHIb at 37 °C. The pathogen cultures are then diluted to an OD₆₀₀ of 0.3 to 0.5 and inoculated 1:10 in semisolid or molten (high temperatures are not recommended) BHIa.

Target isolates must be inactivated by the exposition with 1 mL of chloroform which must be poured onto the plate lid (20 min and 30 min for evaporation of chloroform residues). Finally, 25 mL of BHIa previously inoculated with test microorganisms is poured onto the inactivated isolate. Plates must be incubated at 37 °C for 12–24 h. Inhibition is visualized as a halo around the colonies (Fig. 6).

Dual culture assay

Material

PDA medium

Sterile 0.85% saline solution

Incubator at 28 °C

Fig. 6 Overlay assay basic protocol. Antimicrobial activity was observed in the experiment by the bacterial target isolate against *Candida albicans* (A) and *Bacillus cereus* (B).

Experimental procedure

The evaluation of the biological activity potential of microbes against fungi is based on the cultivation of the target isolate and the pathogenic fungus in the extremities of Petri dishes containing PDA (Machado, 2015; Machado et al., 2020; Silva et al., 2016).

From a precultured fungus, a plug of the mycelium measuring 0.6 cm in diameter is placed on the other top of the plate containing the grown test isolate. As a negative control, a plate containing the phytopathogen was made as a parameter to indicate the time to evaluate the inhibition. The plates are incubated at 28 °C until the complete growth of the negative control (Fig. 7).

Building a natural product extracts library

Material

ISP2 broth
 Potato dextrose broth (PDB)
 Polypropylene mesh
 Amberlite® XAD16 resin
 Methanol
 Ethyl acetate
 Dimethyl sulfoxide (DMSO)
 Centrifuge
 Speed-vac concentrator
 28 °C shaking incubator

Experimental procedure

In this section, we describe the protocol used by Park et al. (2016) to obtain the natural products extract (NPE) from actinobacteria. However, this method might be applied to other bacterial species.

Isolates should be precultured for 3 days at 220 rpm/28 °C in 3 mL of ISP2 broth in round-bottom tubes. Subsequently, a volume of 5 mL of the test isolate preculture should be grown in 250 mL capacity Fernbach flasks containing 100 mL of ISP2. The culture is maintained under the same conditions and the time varies according to test strain. Since the fermentation is done, the cultures must be centrifuged at 4500 rpm for 10 min. Subsequently, the fermentation broth is collected in a new Fernbach flask containing a polypropylene mesh package containing 1.5 g of Amberlite® XAD16 resin (Sigma-Aldrich™). The fermentation broth is then overnight incubated on a rotary shaker under the same conditions. Resin packets are washed in distilled H₂O and transferred to glass tubes (known weight) containing 20 mL of MeOH: EtOAc (1: 1) solution. Finally, the NPEs should be concentrated in Speed-vac and resuspended to the desired concentration in DMSO, and stocked at –80 °C in cryovials.

Concerning fungal natural products, the protocol used in Sharma et al. (2016) is widely reported in several studies and is based on the cultivation of the test fungus in PDB under periodical agitation. However, there are several methods for fungal natural products extraction from in solid-state fermentation (Robinson et al., 2001; Marques et al., 2018; Slaný et al., 2020) to liquid fermentation at static (Silva et al., 2020a; Vieira et al., 2020), partially static (Sharma et al., 2016), or under agitation (An et al., 2020; Tapfuma et al., 2019).

Test fungus' mycelium is transferred and cultivated in 250 mL Erlenmeyer flask containing 100 mL of PDB and stationary incubated at 28 °C in absence of light for 7 to 21 days. After the incubation period, the fermentation broth should be homogenized

Fig. 7 Biological activity in dual culture assay promoted by *Burkholderia* sp. against the phytopathogenic fungus *Ceratomyces paradoxa*.

by adding 10% methanol followed by extraction by ethyl acetate at 1:1 proportion three times. The organic extract is transferred to a known weight tube and concentrated and then resuspended in DMSO (Sharma et al., 2016). Alternatively, the method which employs Amberlite® XAD16 resin can be performed for natural product extraction.

Quantitative evaluation of the biological activity of microbial products

Kirby-Bauer test

Material

BHIb

Müller-Hinton Cation Adjusted (MHCA) agar

Sterile 0.85% saline solution

Sterile and empty antibiogram disks

Incubator at 37 °C

Pachymeter

Media recipes

MHCA

Müller-Hinton Cation Adjusted broth - 22 g/L.

Agar - 15 g/L.

Sterilize by autoclaving for 15 min.

Experimental procedure

Kirby-Bauer test is performed according to the recommendations of Clinical and Laboratory Standards Institute (CLSI, 2017) in triplicates. This method recommends that the Petri dishes containing MHCA agar with 4 mm average thickness. To reach this measure, the following calculation can be applied:

$$V = \pi \cdot r^2 \cdot h$$

where, $\pi = 3,14$, r = Petri dish radius = 8,5 cm, h = Petri dish height = 1,5 cm.

Applying the values to the formula, we obtain the volume of 22.6865 mL of MHCA per plate.

Firstly, the test pathogenic bacterial strains should be cultivated from an isolated colony in BHIb for 12 h at 37 °C. The inoculation of the test strains should be done by spreading (3 to 5 times) the adjusted culture (in 0.85% saline solution) to 0.5 using the McFarland scale using a swab. Afterward, the antibiogram disk is placed on the plate, which is simply paper discs impregnated with known concentrations of antibiotics, crude extract, or pure compounds. Additionally, a positive and negative control should be used for assay validation. Plates must be incubated at 37 °C for 12–24 h. The results might be visualized by a halo around the disk, where the compound efficacy toward the pathogenic bacteria is estimated by the measure of the halo diameter (susceptible: >20 mm, intermediate: 15–19 mm, and resistant: <14 mm) (Fig. 8).

Antagonism index in pathogenic fungi

Material

PDA

Sterile and empty antibiogram disks

Incubator at 28 °C

Pachymeter

Media recipes

PDA

See Section “Isolation of microorganisms from soil, rhizosphere, and plants.”

Experimental procedure

The evaluation of the quantitative antagonism of microbial natural products toward pathogenic fungi is described in Quiroga et al. (2001).

Mycelial plugs of test fungus should be placed in the center of Petri dishes containing PDA, whereas a sterile disk impregnated with a known concentration of test compound placed on top of the plate. As a positive control, we recommend Benomyl, and the negative is represented by the normal growth of the test fungus. The determination of the antagonism index (AI) is based on the calculation of measures of target strain growth using the formula reported by Silva et al. (2016) (Fig. 9).

Fig. 8 Kirby-Bauer test showing antibacterial activity of actinobacteria at 200 µg/disk toward *E. coli* (A), *Bacillus anthracis* (B), Methicillin-resistant *Staphylococcus aureus* (C), and *Listeria monocytogenes* (D). Ciprofloxacin at 200 µg/disk and sterile DMSO are positive and negative control, respectively. Minimum inhibitory concentration

Material

BHIb

MHCA broth

Sterile 0.85% saline solution

Incubator at 37 °C

Microtiter plate reader

Media recipes

BHIb

See Section "Overlay assay."

MHCA

See Section "Kirby-Bauer test."

Experimental procedure

This technique allows the evaluation of the accuracy of the test compound toward a bacterial pathogen, as well as a preview of its mechanism of action (bactericidal or bacteriostatic) (Tortora et al., 2015).

The evaluation of minimum inhibitory concentration (MIC) of microbial natural products is usually performed in triplicates, according to recommendations of CLSI (CLSI, 2018), where test pathogenic bacteria are cultivated in BHIb for 24 h at 37 °C and then diluted in MHCA broth until reach a final concentration of 5×10^5 CFU/mL.

Microbial natural products are diluted in several concentrations and finally added to 96-well plates containing the test pathogen suspensions and incubated for 24 h, at 37 °C. As controls bacterial suspensions in MHCA broth containing 1% DMSO might be used as negative controls, whereas an antibiotic (e.g., ciprofloxacin, tetracycline) as positive. The biological activity is analyzed by the measurement of the optical density of each well 24 h after administration of compounds using a microtiter plate reader.

The determination of the minimum bactericidal concentration (MBC) is based on the subculture of the MIC assay. The wells content (MIC, 2xMIC, MIC/2, and MIC/4) should be inoculated in the center of plates containing MHCA agar without streaking and incubated at the same conditions described. The determination of MBC is based on the calculation of the ratio between the lowest concentration of compound that completely inhibited bacterial growth divided by MIC values. Results less than or equal to 4 are considered bactericidal, whereas above is bacteriostatic (Pankey and Sabath, 2004).

Concluding remarks

Herein, we highlighted the importance of microbes on drug discovery. The biotechnological processes based on microbial metabolism gained notoriety and have increased substantially in recent years for their ability to synthesize plant-derived compounds.

The search for compounds with inhibitory activity against multidrug-resistant pathogens is critically important. In the last decades, synthetic tailoring has been the main strategy to improve the nuclear scaffolding established through analog generation. Although this approach has been beneficial, this line of research has faced a 'Discovery Void' for 30 years, of which no new class of drugs effective against problematic ESKAPE pathogens. In addition, pathogenic microorganisms generally can form biofilms. This cellular superstructure may exhibit greater resistance to antibiotics and cause serious and persistent health problems in humans. This fact that, in recent years, research and development of biofilm inhibitors have become a priority due to the advantage offered by preventing the spread of planktonic cells that can acquire resistance to therapeutic agents, since there are no drugs that have a specific target biofilm in clinical trials to date. Therefore, the possibility to tackle multidrug-resistant infections might decrease the morbidity associated with them and promote an increase in longevity.

It is known that in recent years, research and development of biofilm inhibitors have become a priority. This fact is due to the advantage offered by preventing the spread of planktonic cells. These cells can acquire resistance to therapeutic agents since there are no drugs that have a specific target biofilm in clinical trials to date. Therefore, the possibility to tackle multidrug-resistant infections might decrease the morbidity associated with them and promote an increase in health and longevity.

Introduction

Infectious diseases are considered one of the most important problems of the 21st century, generating epidemiological outbreaks during the last decades (Chin et al., 2020). Infectious diseases are highly influenced by environmental and demographic factors, which play an important role modulating the relationship between hosts and pathogens, and the spread patterns across time and space (Oliveira et al., 2018). The increase in pandemic and/or epidemic outbreaks, as well as the emergence and re-emergence of infectious diseases are highly influenced by climate change, land use change, deforestation, and the increase of human population (Jones et al., 2008; Redding et al., 2019; Halliday et al., 2020). These are factors that may alter (A) the complex interrelationships existing between animal species, (B) the distribution patterns of reservoirs and vectors, and (C) the exposure of humans to pathogens and infectious diseases, due to the continuous increase of population, which is expected to reach 10 billion people by 2050 (Rosenthal, 2009; Redding et al., 2019; Guégan et al., 2020). Nevertheless, the availability of testing and treatments to face these pandemic and/or epidemic outbreaks is very limited in some countries and territories, which represents a challenge for public health planning if we aim to reduce or prevent a serious impact on the population in the future.

In this sense, understanding the relationship between geographical space and infectious diseases could represent a keystone to improve mapping, surveillance, predicting outbreaks in the future, as well as analyzing the spread patterns of diseases (Khan et al., 2012; Scarpino and Petri, 2019). The main components of the epidemiological triad have intrinsic spatial features that can be denoted in hosts, pathogens, and the environment (Hay et al., 2013). Hosts (defined as all organisms capable of harboring another) have a relationship with geographical space that accounts for (Poletto et al., 2012): (A) the movement of infected hosts across the population, (B) the heterogeneous distribution of population vulnerability associated with socioeconomic or cultural characteristics (Hagenlocher and Castro, 2015), (C) the distribution patterns of intermediate hosts (reservoirs) and vectors, (D) the spatial interaction between intermediate and final hosts (Alaniz et al., 2017a,b). On the other hand, the pathogen (defined as the agents that cause disease, illness, or injury) also has an intrinsic relationship with geographical space, which is closely related to its interaction with hosts and environment, for example: (A) potential mutational changes due to environmental characteristics and host density, (B) the ability to survive in different environments, (C) geographical distribution of its reservoirs and vectors (Rosenthal, 2009). Finally, the environment has an important role modulating the conditions for disease development, which can be altered by human impacts, thus providing suitable conditions for disease emergence linked to ecosystem destruction, pollution, overcrowding, temperature increase (due to climate change), among others (Khan et al., 2012).

These links between infectious diseases and their geographical dimension need to be explored and conceptually clarified, allowing to increase the capacity of decision making in public health based on the implementation of epidemiological modeling and predictive tools (Khan et al., 2012; Hay et al., 2013; Scarpino and Petri, 2019). In this chapter, we present an up-to-date conceptualization of infectious diseases from a geographical approach.

Spatial dimension of infectious diseases

Infectious diseases are determined by the interactive effects of three components defined as the epidemiologic triad, which includes the host, the pathogen and the environment (Engering et al., 2013). In this section we explored the geographical dimension of each component.

Georeferencing host

The host is defined as individuals susceptible to acquiring a pathogen and developing (or not) the disease. From a conceptual approach, there are different types of hosts: (A) animal hosts, which are mainly reservoirs and vectors that act as intermediate hosts for pathogens and (B) clinical hosts, which are humans that acquire the pathogen. These hosts have differences from a geospatial dimension.

In the case of animal hosts, a large proportion of individuals (mainly wildlife such as bats, rodents, monkeys, etc.) is not tested and their geographical records usually remain only as georeferenced occurrences (Escobar, 2020). This generates uncertainty in terms of the positivity of wildlife animals, so that it is possible only to access the distribution of potential hosts, but not corresponding to the actual distribution of infected reservoirs (Astorga et al., 2018). In fact, this type of data is in the public domain, freely available and easily accessible through platforms such as Global Biodiversity Information Facility (<https://www.gbif.org/>) and the Malaria Atlas (<https://malariaatlas.org/>) (Robertson et al., 2014). On the other hand, for zoonotic diseases transmitted by domestic and livestock animals, testing is much more implemented and tracked. However, the obtained data for these cases is not widely and publicly distributed, and the access to geographical coordinates is less common (Chand, 2021).

In the case of human hosts, there are sub-components related to their vulnerability such as comorbidities, nutritional status, behavior, genetic susceptibility, and immunological capacity, which could be georeferenced from patients' clinical records (Beck et al., 2004; Trammell and Toth, 2008). Additionally, positivity for infectious disease may be also georeferenced by public health governmental agencies. However, not all diseases can be georeferenced with a spatially explicit latitude/longitude or address because the privacy protection of patients is only available at regional or sub regional levels (Hollis, 2016). On the other hand, sub-components related to socioeconomic vulnerability that have an important link to infectious diseases are also georeferenced in national and subnational censuses and cadastres (Mareze et al., 2019). This information is usually available on a square scale from censuses and could be useful for modeling host vulnerability.

Georeferencing pathogens

This component corresponds to disease generating agents including viruses, bacteria, fungi, protozoa, and prions, among others. These agents have different characteristics linked to transmissibility, pathogenicity, virulence, and toxicity, among others, which determine their potential for spreading throughout the population and geographical space (Casadevall and Pirofski, 2001). The biological cycle of transmission of these agents could be closely linked to the geographical space, which could be classified into the following non-exclusive types:

- (A) Vector or reservoir driven agents: Vector-borne infectious diseases are maintained in nature through the interaction between vertebrate and invertebrate species, the latter usually being a hematophagous arthropod organism acting as an intermediate host (mosquitoes, ticks, fleas, and kissing bugs, among others) that could transmit a pathogen to a final host, either animal or human (Sadeghieh et al., 2020). This type of disease affects over than 1 billion people annually (Fig. 1), some examples of epidemiological importance include: (i) mosquitoes (Fig. 1A), one of the most important vectors for several diseases in the tropical zone, transporting viruses responsible for malaria, chikungunya, West Nile fever, Zika, yellow fever, Japanese encephalitis, and lymphatic filariasis (Franklinos et al., 2019); (ii) Kissing bugs (Fig. 1B), an important source of contagion of the protozoan *Trypanosoma cruzi* which is the etiological agent of Chagas diseases in the Americas (Klotz et al., 2014); (iii) Ticks (Fig. 1C), the main cause of several diseases in North America and Europe, being associated with Lyme disease, anaplasmosis, babesiosis, ehrlichiosis, Powassan virus disease, borrelia, Rocky Mountain spotted fever and tularaemia (Walker, 2014). On the other hand, agents may also be transported by vertebrate reservoirs; examples of epidemiological importance include: (i) bats (Fig. 1D), considered important carriers of agents that can produce disease, such as Coronaviridae (SARS, MERS), Rhabdoviridae, Paramyxoviridae, Astroviridae, Adenoviridae, and 21 other virus families (Fig. 2; Letko et al., 2020); (ii) rodents (Fig. 1E), related to a variety of diseases such as Hantavirus, haemorrhagic fever, Lassa fever, leptospirosis, lymphocytic choriomeningitis, omask haemorrhagic fever, plague, rat-bite fever, salmonellosis, South American arenaviruses, and tularaemia (Astorga et al., 2018; Rabiee et al., 2018).
- (B) Agents in the environment: Different agents may include environmentally free steps in their biological cycles, where they may remain until they infect a host. This type of agents may remain in trees, air, soil, or water until infecting an animal or human host; examples of epidemiological importance include: (i) Fungal agents such as *Cryptococcus* spp. (Fig. 1F), which can change form between yeast and hyphal, the latter being capable of releasing spores that can be present on trees until inhaled by domestic animals or humans. This agent is responsible for cryptococcal meningitis that mainly affects immunosuppressed patients (Carvajal et al., 2020). (ii) Schistosomiasis (Fig. 1G), which is a disease caused by a trematode parasite that produces acute or chronic inflammation of tissues, commonly affecting the liver, intestines, and the bladder. Its eggs are shed from infected humans via feces and urine to the aquatic environment, where they hatch and release miracidia that penetrate the tissues of water snails. This disease is closely linked to poor water sanitation in African countries, and about 290.8 million people requiring treatment during 2008 (Leshem et al., 2008). (iii) Enteric pathogens (Fig. 1H), such as *Cryptosporidium parvum* and *Giardia* spp. The latter is a flagellated protozoa responsible for gastrointestinal symptoms and can also produce chronic enteric disease. The infective cysts of *Giardia* spp. may be present in water, food or hands/fomites, and may affect over 200 million people per year (Cacciò et al., 2005).

Fig. 1 Vectors, reservoirs, and pathogens. (A) Kissing bug (*Triatoma* spp.), (B) Deer tick (*Ixodes scapularis*), (C) Mosquito (*Anopheles* spp.), (D) Bat (*Pteropus vampyrus*), (E) Rodent (*Oligorhizomys longicaudatus*), (F) fungal pathogen (*Cryptococcus neoformans*), (G) reservoir snail of *Schistosoma mansoni* (*Biomphalaria* spp.), (H) enteric parasite (*Gardia* spp.)

(C) Human to human infectious diseases: This type characterizes to a series of diseases with a transmission cycle linked to humans, in which animals are not involved or were involved only during the initial phase of transmission. This type of infectious disease may have multiple transmission pathways including sexual, airborne, transplacental, and blood transfusion, among others (Wolfe et al., 2007). In this case, the transmission pathway is highly relevant to the spatial dispersion of the disease, which is also influenced by other factors related to the agent discussed above. A high proportion of respiratory diseases fall into this category, such as influenza, respiratory syncytial virus, adenovirus, parainfluenza, while sexually transmitted diseases are also within this category (gonorrhea, HIV, herpes, hepatitis, among others; Vink et al., 2014; Workowski and Berman, 2011). A relevant case is COVID-19, which reached the category of pandemic due to its high dispersal capacity associated with the characteristics of the virus characteristics, as well as the time of onset of symptoms onset and its low mortality but high infectivity. The origin of this virus is still under discussion; however, the extensive scientific background supports the hypothesis of an animal origin linked to pangolins and bats (Wiersinga et al., 2020).

Fig. 2 Example of georeferencing occurrences of two bat species considered reservoirs of the Ebola virus in Africa.

Modulating environment

Agents and hosts interact within an environmental space, which modulates the generation of diseases. In the natural environment, pathogens are usually found in a pseudo-equilibrium state that derives from biodiversity, in which effects such as dilution and nidity are present (Halliday et al., 2020). First, the dilution effect is responsible for reducing the proportion of susceptible hosts in the ecosystem, thus reducing the spread of the pathogen spread throughout the ecological assemblage (Halliday et al., 2020). On the other hand, natural nidity is related to the stable circulation of the pathogen in the ecological community, which reduces the stochastic effects that could produce an outbreak. Human impacts on biodiversity may alter nidity and dilution effects by reducing the species and genetic diversity; the most important drivers are: (i) physical-chemical habitat degradation, (ii) habitat destruction and fragmentation, (iii) arrival and colonization of invasive species, (iv) migrations to new habitats, among other (Halliday et al., 2020).

On the other hand, climatic, meteorological, and atmospheric variables are also important for the relationship between host and pathogen. A high proportion of diseases are constrained due to climatic characteristics related to temperature and humidity, important factors that determine suitability for pathogens, vectors, and reservoirs in different environments (Rosenthal, 2009; Escobar and Craft, 2016). As climate change is projected to generate significant shifts in global climatic configuration, these changes will affect all the living organisms on the planet, including pathogens (Wu et al., 2016). Finally, at the local scale, environmental characteristics related to the quality of life in urban and rural areas also have an important influence on the potential generation of epidemic or pandemic outbreaks (Redding et al., 2019). These factors include air quality and overcrowding, which can increase the vulnerability of hosts to pathogens (Redding et al., 2019).

Spatial modeling and infectious diseases

Ecological niche modeling

A widely used approach to modeling biological organisms is ecological niche modeling, with an origin applied to ecological and biodiversity conservation sciences (Guisan et al., 2013). However, it has been recently used for modeling infectious diseases, mainly to estimate the potential distribution of vectors, reservoirs, and pathogens (Fig. 3; Escobar and Craft, 2016; Escobar, 2020). This approach is supported by the niche theory, which suggests that biological organisms have different biotic and abiotic requirements linked to food, refuge, environment, and biological interactions, among others (Soberon and Nakamura, 2009). These requirements are stable on short timescales because they are the end result of thousands or millions of years of evolution, so they cannot change on the human timescale. Theoretically, there are multiple types of ecological niches (Eltonian, Grinnellian, and Hutchinsonian); however, the most accepted approach is the one presented by Evelyn Hutchinson in 1954, who defined the ecological niche as the N-dimensional space of variables in which the fitness (biological adequacy) of organisms is positive

Fig. 3 Diagram of ecological modeling function to predict habitat suitability (red colors means high suitability).

(Colwell and Rangel, 2009). This means that within this N-dimensional hypervolume, the population will increase (high natality and low mortality), while outside, it will decrease. The ecological niche is an intrinsic property of organisms (each individual has its own niche), thus this individual niche could be averaged at a population, metapopulation, or even a species level (Soberon and Nakamura, 2009). This theory also identifies two different types of niche: (A) potential niche, which corresponds to the entire N-dimensional space of variables in which a species has a positive fitness, in absence of ecological interactions with other species. (B) Realized niche, which corresponds to the proportion of the N-dimensional space that the species effectively uses due to restrictions derived of ecological interactions with other species (competence, predation, mutualism, etc.; Soberón, 2007; Soberon and Nakamura, 2009).

Modeling procedures consider the use of georeferenced occurrences of the organism, which is combined with a set of environmental predictor variables (Fig. 3; Guisan et al., 2013). Then, these datasets are combined by using a modeling algorithm, which can be based on linear statistical modeling, interpolation, or machine learning. The latter methodological approach has been the most widely used, including algorithms such as the boosted regression tree, random forest, support vector machine, and maximum entropy (Hirzel and Le Lay, 2008). MaxEnt is the most used software for modeling species niche, which uses environmental layers in raster format (.asc) and a table with the name of the species and the latitude and longitude of each record (.csv) (Phillips et al., 2006). These models have a protocol that considers the reduction of spatial autocorrelation of occurrences that helps to reduce sampling biases, and the reduction of variable collinearity to avoid model overfitting (Alaniz et al., 2017a,b; Carvajal et al., 2020). The final results include a map of habitat suitability for the species and the relationship between the predicted suitability with each used environmental predictor variable (Peterson and Soberón, 2012). The latter product is highly useful to interpret ecological and biological requirements of the modeled organism. The initial models only considered bioclimatic variables, but most recent studies have integrated them with detailed satellite data showing information on air pollutants, biophysical parameters of the ecosystem, soil characteristics, and meteorological conditions, among others (Anderson, 2017; Alaniz et al., 2020). This has promoted an increase in the quality and predictive power of these types of model, which usually select variables taking into account the biology of the reservoir, vector, or pathogen they are trying to model.

The predicted suitability of MaxEnt can be homologated to the potential abundance of the organism, then they can be combined with human population density maps, allowing to estimate the potentially exposed population (Alaniz et al., 2017a,b, 2018). This means that in areas where the model predicts high reservoir, vector, or pathogen suitability, and these areas coincide with high population density, the exposure risk will be higher (Fig. 4).

These models are also useful to predict the potential distribution of a reservoir, vector, or pathogen in zones that have been recently colonized, or even before the colonization (Escobar and Craft, 2016; Escobar, 2020). This is generated by considering the niche conservatism principle mentioned above. Finally, these models can predict the future distribution of reservoirs, vectors, and pathogens by integrating global circulation models of climate change as predictor variables (Elith et al., 2010). Both analyzes could be of great use in designing preventive actions in the event of the possible arrival or expansion of the geographical distribution of the pathogen. In fact, this has multiple advantages for spatial prioritization of tests and treatments, which will be discussed below.

Fig. 4 Diagram of spatially explicit estimation of risk by combining suitability model of pathogens with layers of human population (vulnerability) in a GIS environment. This framework includes the consideration of particular risk groups based on their vulnerability to become infected or develop the disease, as well as population density.

Bayesian modeling

Bayesian spatio-temporal analysis allows the study of space-time changes and pattern of diseases, considering spatial analysis units and time-series that enable identifying areas or time periods in which risk could increase (Wah et al., 2020). This approach addresses several problems that frequentist statistics present when modeling diseases, related with spatially structured errors, non-linearity of trends and data, small sample size, or missing data (Baptista et al., 2016). These models can use the number of cases or deaths to obtain variables such as relative risk of incidence, survival time, or mortality, incorporating covariates such as demographic, socio-economic, life styles, clinical, meteorological, environmental and health access variables (Wah et al., 2020). There are several types of model such as generalized linear mixed models, P-spline and B-spline models, the Poisson log-linear model with clustering and smoothing components, the transformation class of spatio-temporal cure rate CAR survival models, and the Besag, York, and Mollié (BYM) moving average model. The BYM model allows incorporating random effects associated with: (A) unstructured errors, linked to the potential correlation between variables or time series and (B) structured errors, derived from spatial clustering of data or adjacency of spatial analysis units (Samat and Mey, 2017). Adjacency matrices of spatial analysis units are incorporated to generate BYM models, which are used to deal with structured errors. This model considers spatial analysis units, which usually correspond to administrative units such as municipalities, districts, or regions, using as input data the total number of cases or deaths accumulated for each spatial unit for a determined time period (day, week, month). As output, the models show the spatial and temporal patterns of the estimated variable (e.g., mortality or incidence), also showing the level of correlation and the importance of each covariate for risk estimation (Samat and Mey, 2017; Aswi et al., 2019). This allows us to estimate the influence of different factors on the relative risk, which could inform public health actions in prevention, control and management (Aswi et al., 2019).

Applications (API)

Recently, the situation arising from the COVID-19 pandemic has prompted national and international health agencies to share information publicly through websites. This type of visualizers are developed using different API development tools such as ArcGis Online and Google Earth Engine, which provide an interactive platform for publishing maps and spatial information on infectious diseases. An example of this is the John Hopkins University's COVID-19 map, which was launched in the initial phase of the pandemic and has been active for about 2 years, providing useful information about the disease (<https://coronavirus.jhu.edu/map.html>) (Hay and Snow, 2006). Another example is the explorer of the MalariaAtlas project (<https://malariaatlas.org/explorer/>), which provides spatial data on multiple dimensions of malaria disease, including vectors, prevalence, and human population factors, among others.

Regarding COVID-19, multiple countries have implemented visualizers with information at the national level information, providing statistics on daily incidence and mortality, and sharing statistics on vaccination (Franch-Pardo et al., 2020). This type of APIs could also be implemented for mobile platforms (Android, IOS), allowing users to share information about vectors and reservoirs (Saran et al., 2020).

GIS processing

Another widely used tool for analyzing spatial dynamics of infectious diseases are the Geographic Information Systems (GIS), which provide an interface for managing, processing and analyzing spatial data. GIS have a wide variety of geoprocessing applications that can be useful for overlapping layers of different spatial information, allowing to identify spatial patterns and congruences (Khashoggi and Murad, 2020; Saran et al., 2020). Popular software such as ArcGIS, SAGA GIS, and QGIS have a wide range of geoprocessing tools that allow implementing interpolations, principal components analysis, spatial clustering analysis, clipping, merging, dissolution, and geographically weighted regressions, among others. In fact, GIS is very important for linking information from different sources such as tables, ecological niche models, population density grids, cadastres, and censuses (Khashoggi and Murad, 2020). As a result, GIS offers the possibility of processing these data and obtaining new products, such as (A) risk level maps, by combining niche models with population data (Fig. 4), (B) shift in pathogen distribution derived from climate change, (C) interpolation of cases to generate incidence maps, (D) joining maps of administrative units with clinical record charts, among other (Khashoggi and Murad, 2020).

Data collection

Spatial modeling of infectious disease requires georeferenced data to generate predictions in time and space, which can be typically sparse depending on the specific disease (Escobar, 2020). Clarifying data sources for reservoirs, vectors, and human cases, could be an important tool for epidemiological modeling (Escobar, 2020). In this regard, an important issue related to determining the location of the pathogen, which could be found within humans, animals, or in the environment (Escobar and Craft, 2016; Escobar, 2020). For the case of pathogens inside humans, the best source of data could be obtained from health centers (hospitals or primary centers) that have individual clinical records of each patient detailing current and past pathologies. Typically, health centers serve patients in certain geographical areas, having certain jurisdiction or areas of influence that may be linked to community territorial

units (Cramer et al., 2020). These clinical records information on comorbidities, address, age, sex, and pathologies of each patient, which could be useful at governmental level or for scientific studies (considering informed consents; Emanuel and Boyle, 2021). In this sense, due to ethical and privacy constraints this information is usually available at coarse territorial level (municipality, district, or region; Hollis, 2016). For reservoir- and vector-driven zoonotic diseases, an important assumption for modeling is that all individuals of the target species could carry the pathogen. Information may be available from multiple sources: (A) veterinary records, which have a clinical history of animals similar to that of human clinical records but with less detail, there is generally a bias in the availability of these records for domestic animals (mainly dogs and cats); (B) livestock animals, which are under continuous monitoring to avoid potential outbreaks arising from zoonotic pathologies, this group corresponds mainly to pigs, cows, goats, and chickens. In this case, if a zoonotic pathogen is detected, governmental agencies proceed to report the specific location of the infected animals, which is also followed by appropriate sanitary measures (Beard et al., 2018); (C) wildlife animals, in this case, the largest proportion of records are derived from studies that focus on biological aspects of the organism, which may be found in scientific publications, publicly available data collections, and records compiled through citizen science (Escobar and Craft, 2016). Most of these records are not created for epidemiological purposes, so the availability of data on pathogen positivity in these animals is highly restricted to certain species, and may be found in specialized scientific studies (Escobar, 2020). Finally, in the case of pathogens in the environment, the availability of records is very restricted, which could be developed after an epidemic outbreak in order to find the origin of the pathogen (Carvajal et al., 2020). This could also be developed by health agencies to monitor water quality, which lead to the identification of pathogens collected in samples. These records are hardly shared by governmental agencies and may be found in specialized scientific studies and official governmental publications.

Spatial prioritization of resources

Spatial information is valuable for public health policy and management because, as we have shown above, infectious diseases have an intrinsic relationship with geographical space. In a large proportion of countries around the world, public health systems are operating at the limits of their capacity, due to the large number of emerging and re-emerging infectious diseases and the limited availability of resources to provide adequate screening and treatment (Elsharkawy et al., 2018). This has evidently intensified in the aftermath of the COVID-19 pandemic, where proper testing, traceability, and treatment is essential to provide adequate care for all infected patients (Franch-Pardo et al., 2020; Wiersinga et al., 2020). In fact, previous epidemic outbreaks have also shown the need to prioritize resources such as in the case of *Cryptococcus* in Canada during 1999, SARS in China in 2003, MERS in the Middle East during 2012, Ebola Virus in Guinea during 2014, and Zika virus in Brazil during 2017 (Verma, 2003; Alghamdi et al., 2014; Uejio et al., 2015; Alaniz, 2019; Letko et al., 2020). On the other hand, a large proportion of pathogens are responsible for a high and stable number of infected patients globally, forming part of an endemic transmission cycle such as malaria, schistosomiasis, hantavirus, Chagas disease, and Lyme disease, among others (Medley and Vassall, 2017). We classify the contribution of spatial data to public health into four main points:

- (A) Management plans: Public health systems must be prepared to respond to endemic pathogens, which may have specific patterns in space and time. Management plans include annual vaccination campaigns against recurrent viruses that have a seasonal behavior (e.g., influenza; Klepser et al., 2019). Countries often have a list of recurrent diseases that are included in public health care programmes for the population; for these pathogens, spatial information could be very useful because risks have a heterogeneous spatial distribution (Jones et al., 2008; Medley and Vassall, 2017). In this sense, having the specific information on the risk of exposure to different pathogens could be useful to allocate medical supplies and focus efforts on the most exposed population (Alaniz et al., 2017a,b). Additionally, all information generated should be recorded and spatially registered, which, at the same time, will provide more data to improve spatial models as feedback to improve public health management (Fig. 4).
- (B) Preventive plans: Prior to the occurrence of an epidemic outbreak, spatial modeling of infectious disease can be very useful to detect areas where pathogens have high suitability (Saran et al., 2020). On the other hand, mapping of initial cases could provide information on their spatial distribution representing an initial phase of a potential outbreak (Hafeez et al., 2017). Although the occurrence of an outbreak is a highly stochastic process, having this information allows the health system to be prepared for an eventual case (Scarpino and Petri, 2019). This information should motivate public health agencies to implement education and informative campaigns, as well as to prevent or avoid actions in these high-risk areas that could trigger an outbreak (Beard et al., 2018). An example of this was the Nipah virus in Malaysia during 1999, where deforestation and urbanization of the native habitat of *Pteropus vampyrus* bats triggered an epidemic outbreak with high lethality (Epstein et al., 2020).
- (C) Response plans: Following the occurrence of an epidemic or pandemic outbreak, urgent actions by public health agencies should focus on controlling the spread of the pathogen across space and population (Saran et al., 2020). In this sense, spatial information provides essential tools to improve decision making processes in response to the outbreak, by prioritizing resources in areas of high incidence, or by increasing preventive actions in areas where the pathogen have not yet arrived (Carvajal et al., 2020). On the other hand, spatial data on incidence or number of critically ill patients is essential to allocate resources such as hospital beds, medicines, health professionals, and testing supplies (Sun et al., 2020). An example of this has

been the current COVID-19 pandemic outbreak, where spatial information has played an important role in decision making on lockdowns and quarantine, as well as the allocation of medical supplies (Franch-Pardo et al., 2020; Sun et al., 2020).

Advantages and limitations

Spatial modeling is a useful tool for public health planning, providing information to develop appropriate policies related to the allocation of treatments, medicines, and professionals. On the other hand, it is important for developing preventive and control actions in the face of possible epidemic or pandemic outbreaks. In this sense, the main advantage is related to the optimisation of limited resources, a common scenario in developing countries.

There are certain limitations of spatial modeling that need to be discussed if we expect a correct interpretation of its results. One example is the collection of information from clinical records, which present different problems, such as the georeference of infected individuals and the lack of standardization of questionnaires (Crameri et al., 2020). In the case of georeferencing infected individuals, the acquisition of this data could be problematic due to ethical constraints, especially the clinical records of patients suffering from the disease that could be socially stigmatized (Hollis, 2016). A possible solution to this could be to provide this data at a higher administrative level (municipality, district or region), and in completely anonymous terms in order to protect the privacy of patients (Hollis, 2016). Another problem is the lack of standardized questionnaires for clinical diagnosis and records, which often vary between countries or even within countries when patients are treated in public or private health facilities (Emanuel and Boyle, 2021). A solution to this is the generation of international standards that are commonly used in other fields, such as safety and quality (similar to ISO standards). Additionally, countries should have a health policy that demands public and private health centers to apply the same questionnaires, with the aim of accessing homogenous information that is useful for the improvement of health programmes (Chin et al., 2020). Finally, another important limitation is related to the scarcity of systematic sampling of pathogens in the environment, as well as reservoirs and vectors (Fig. 2; Escobar and Craft, 2016). We recommend that countries implement systematic sampling programmes with a multidisciplinary approach, combining the efforts of governmental health, agricultural, and wildlife agencies to generate this information.

Future perspectives

Currently, geography is essential to medicine and public health because it enables understanding different phenomena related to the spread of disease, infection, and mortality through space and time. In recent decades, an explicit relationship has been identified between geographical transformations resulting from anthropogenic activities and the emergence or re-emergence of infectious diseases. In this chapter, we highlight the conceptual and theoretical links between geography and infectious diseases, showing how each component of the epidemic triad (host, pathogen, and environment) could be linked to a spatial dimension. Our aim is to provide clear information on spatial modeling to medical and health professionals, decision makers, and students, aiming to broaden their knowledge on this interesting topic.

Infectious diseases have represented one of the main challenges for human population for centuries, from the black death in the 14th century, to acquired immune deficiency syndrome (AIDS) in the 80s, and the current COVID-19 pandemic. Estimates suggest that millions of people die annually from infectious diseases, such as respiratory diseases, AIDS, diarrhoeal, tuberculosis, and malaria, among others. As populations continue to grow and ecosystem degradation continues, we expect infectious diseases to continue to emerge and re-emerge, which could have considerable impacts on economies and societies around the world. Enormous advances in data science and computational processing power represent a powerful tool in the fight against infectious diseases, as 1980 satellite technology and GPS enable spatial tracking of countless parameters and data. Moreover, the recent development of more complex and accurate modeling approaches opens new frontiers on the study of infectious diseases. In fact, it is necessary to advance in the implementation of these new tools, considering that pathogens are continuously evolving and changing their ecological niches much more rapidly than their hosts. On the other hand, the new climatic conditions imposed by climate change poses a highly unpredictable scenario, where we do not have enough knowledge on how pathogens would react or adapt. The development of predictive models of already known pathogens is important for preventive actions against possible outbreaks, which should be accompanied by the development of new and more effective surveillance, diagnostics, vaccines, and treatments. In fact, the current COVID-19 pandemic has highlighted how linking geography and medicine could provide effective solutions against the scarcity of resources and the dynamic changes of the disease across the population.

The mechanisms underlying the increase in infectious diseases over the last decades, which is undoubtedly related to alterations of natural ecosystems and human overpopulation, need to be sought. In this sense, humanity needs to incorporate a respectful attitude towards biodiversity, acknowledging its regulatory role over pathogens and the biological cycle of these infectious diseases. We believe that paradigm shift is necessary to ensure the future survival and well-being of the human population, which must include the harmonious coexistence with all other living organisms on earth.

Introduction

Resistance of human bacterial pathogens to one or even more antibiotics is rapidly emerging and represents a severe world-wide health problem. At the same time, the discovery of new targets allowing the development of novel antibiotics is hampered due to the lack of economic incentives and redundant hit compounds in drug screening programs based on established platforms (Lakemeyer et al., 2018). Therefore, innovative ideas exploiting new methodological approaches are urgently needed. Metabolism and especially the central carbon metabolism could provide a promising and alternative field for drug discovery due to several reasons (Murima et al., 2014): (i) Metabolic transformation of nutrients to afford energy (e.g., ATP) is largely related to virulence of many pathogens as well as persistence of bacterial infections (Eisenreich et al., 2017; Best and Abu Kwaik, 2019; Eisenreich et al., 2019, 2021). (ii) Bacteria partially rely on different metabolic pathways in comparison with their human host cells (Rohmer et al., 2011). It is therefore intriguing to develop drugs against metabolic enzymes of unique bacterial pathways, since inhibition of these reactions are believed not to cause severe side effects in humans. (iii) Since metabolism controls the emergence of bacterial persistence (Eisenreich et al., 2021), sophisticated inhibitors against the key reactions involved in this axis play an important role in the future. (iv) Reprogramming the central carbon metabolism of human pathogens by innovative drugs increases the susceptibility to known antibiotics (Stokes et al., 2019; Liu et al., 2019).

Unfortunately, the metabolism of bacterial pathogens is poorly characterized, although the genome sequences of the major pathogens are known in considerable detail. However, knowledge about the metabolic capabilities based on genome annotations of metabolic enzymes does not necessarily consider all metabolic reactions being functional especially under the conditions of actual infections. Therefore, more analytical techniques have been developed for the full assessment of the metabolic pathways being active in a cell even under complex conditions. These techniques include (i) transcriptomics, (ii) proteomics, (iii) metabolomics, (iv) ^{13}C -flux analysis and isotopologue profiling.

Transcriptomics, which nowadays mostly refers to RNA sequencing, and proteomics allow quantitative and full coverage of the cellular transcriptomes and proteomes, respectively. Studies using these techniques have also shown high reproducibility in inter-laboratory comparisons (Collins et al., 2017; Giraldez et al., 2018). In contrast, metabolomics is still limited to a few hundred compounds out of the thousands of compounds comprising the whole metabolome (Zamboni et al., 2015) and quantitative metabolic profiles are difficult to replicate (Mirsaeidi et al., 2015). While proteins and RNA-transcripts can be quantitatively extracted, the structural diversity of metabolites prevents a unified extraction protocol for a given metabolome (Nielsen, 2017). Additionally, the metabolome is most directly affected by environmental changes leading to high turnover of metabolites (Zamboni et al., 2015). In comparison to metabolomics, the determination of metabolic fluxes (fluxomics) and ^{13}C -based pathway analyses (isotopologue profiling) typically rely on smaller subsets of metabolites and are therefore easier to be standardized. To combat the issue of high metabolite turnover, protein-bound amino acids are mostly used in isotopologue profiling studies since they are stable, can be easily extracted and are highly abundant in cellular material (Sauer, 2006).

While transcriptomics can be routinely performed with low numbers of cells through RNA amplification (Lowe et al., 2017; Lafzi et al., 2018), proteomics and metabolomics typically require several mg of dried cells (Allwood et al., 2013; Mertins et al., 2018). Here, the sensitivity of mass spectrometers, even more of nuclear magnetic resonance (NMR) spectrometers is still limiting, but applications for single-cell proteomics and metabolomics are quickly improving (Kumar et al., 2020; Cong et al., 2020). Fluxomics based on protein-bound amino acids also requires relatively high numbers of cells (about 0.2 mg of dry cells) for analysis (Long and Antoniewicz, 2019).

When using these -omics techniques to analyze cellular metabolism it is important to take into account two levels of control that influence metabolic fluxes: (i) Hierarchical control due to transcription, expression and post translational modifications.

(ii) Metabolic control by metabolites themselves (Nielsen, 2017). Hierarchical control can be analyzed by transcriptomics and proteomics while metabolic control can be assessed by metabolomics. However, to correlate metabolic control with the respective conditions, for example during infections with bacterial pathogens, knowledge about the actual metabolic fluxes is necessary. Although flux analysis covers the smallest subset of cellular compounds, it offers the highest potential to characterize metabolic processes being actually active in considerable detail. Thus, a transcriptome does not easily give information on post-translational modifications of proteins, which are often crucial for enzyme activation. Furthermore, the quantification of proteins alone does not necessarily allow to infer active metabolism reactions due to their various kinetic properties and metabolic control mechanism. At the same time, the amounts of metabolites can also provide ambiguous information, since they do not directly reflect the metabolic turnover in specific pathways due to their potential multiple roles in different pathways (Sauer, 2006). Therefore, isotope-based flux analysis seems to be the most robust method that allows the direct analysis of substrate usage and the core metabolic pathways in a living cell. It becomes more and more clear that pathogens utilize a variety of carbon substrates from their specific environments during the infection cycle. More specifically, each bacterial pathogen appears to exploit a specific sub-set of these compounds to drive a metabolic network that is highly adapted to the respective replicative niche during infection (Abu Kwaik and Bumann, 2015; Abu Kwaik, 2015; Eisenreich et al., 2015; Olive and Sasseti, 2016; Escoll and Buchrieser, 2018; Best and Abu Kwaik, 2019; Eisenreich et al., 2019; Traven and Naderer, 2019). This adaption is typically manifested in form of a so-called bipartite metabolism (Grubmüller et al., 2014; Häuslein et al., 2016, 2017a; Mehltitz et al., 2017; Eisenreich et al., 2017; Best and Abu Kwaik, 2019; Rajeev et al., 2020). In this apparently divided metabolic network, one or a set of substrates serve to build up cell wall sugars, nucleotides and lipids, whereas another substrate or a subset of substrates is utilized to afford energy (e.g., ATP). Noteworthy, using isotopologue profiling this metabolic model was determined for several pathogens, especially for intracellular bacterial pathogens.

In this review, we focus on methods of pathway analysis by ^{13}C -isotopologue profiling. In the first section, we describe some basics and typical protocols for isotopologue profiling. In the second part, this technology will be illustrated by several recent examples especially with intracellular bacterial pathogens.

Basics about ^{13}C -isotopologue profiling

To perform isotopologue profiling, a bacterial pathogen is cultivated in the presence of a ^{13}C -tracer, i.e. a compound that is artificially ^{13}C -enriched beyond its natural abundance (for ^{13}C , the natural abundance is 1.1%). Uptake and metabolic utilization of this tracer by the pathogen lead to ^{13}C -enrichments in any metabolic product being involved in this conversion process, i.e. metabolically located downstream from the tracer. As a result of the specific pathways being involved in this process, the positional distribution of the ^{13}C -label in the metabolic products is not random, but rather highly specific. In other words, highly specific mixtures of $^{12}\text{C}/^{13}\text{C}$ stable carbon isotopologues (i.e., ^{13}C -profiles or ^{13}C -patterns) are formed by the pathways being functional under the respective experimental conditions. On the basis of these ^{13}C -profiles, the metabolic history (i.e., substrate usages, catabolic and anabolic pathways, relative carbon fluxes) from the source to each respective metabolite under study can be determined.

According to IUPAC definition, isotopologues have the same chemical structure and bond connectivity but differ only in their isotopic composition. For example, acetic acid comprising the abundant ^{12}C -atoms, $^{12}\text{CH}_3^{12}\text{COOH}$, and acetic acid containing ^{13}C at the methyl group, $^{13}\text{CH}_3^{12}\text{COOH}$, are different carbon isotopologues of acetic acid. Isotopologues can be further sub-grouped into isotopomers, which have the same chemical structure, same bond connectivity and the same number of isotopes, but the isotopic atoms differ in terms of their position within the molecule, for example $^{13}\text{CH}_3\text{COOH}$ and $\text{CH}_3^{13}\text{COOH}$. In theory, a compound with n C-atoms can produce 2^n carbon isotopologues. For example, glucose can be grouped into 64 different stable carbon isotopologues. This large number of isotopologues behind every metabolite in the metabolome of an organism multiplies to an almost infinite number of ^{13}C -isotopologues, thus enabling to describe the metabolic system under study at high resolution, even with a limited number of metabolites being used for isotopologue profiling.

Isotopologues can be identified and quantified by NMR spectroscopy or mass spectrometry (MS). For work with intracellular bacteria, mass spectrometry (i.e., gas chromatography-MS (GC-MS) or liquid chromatography-MS (LC-MS)) is the preferred method due to its higher sensitivity. Using mass spectrometry, metabolites under study are typically described by their mass distributions, i.e. isotopologues are denoted as M when only ^{12}C is present, while sets of the respective ^{13}C -isotopologues are indicated by $M + 1$, $M + 2$, ..., $M + n$ when n ^{13}C -atoms are present in the molecule. Accounting the relative fractions of isotopologues then affords the overall ^{13}C -excess of the metabolite under study. ^{13}C -Excess here means the overall percentage of ^{13}C in a molecule minus the natural abundance contributions. Following the nomenclature for isotopologues introduced above, the ^{13}C -excess is calculated with the following formula (Lee et al., 1991).

$$\text{Excess} = \frac{\sum_{i=1}^n (M + i) \times i}{n}$$

General principles, constraints and guidelines for designing isotopologue profiling experiments

Some basic assumptions have to be made for ^{13}C -isotopologue profiling in bacteria:

- (i) **Kinetic isotope effects:** In metabolic reactions, there is a small discrimination between ^{12}C and ^{13}C due to small kinetic isotope effects (Kamen, 1947; Whelan et al., 1970). However, these effects are minor in comparison to the typical incorporation rates of ^{13}C -enriched substrates from the environment in labeling experiments. Roughly, in terms of ^{13}C -excess values $>0.5\%$, effects due to kinetic isotope effects are within the errors of ^{13}C -quantification and can therefore be neglected (Antoniewicz et al., 2007).
- (ii) **Steady state conditions:** In standard long-term experimental settings (see below), isotopic as well as metabolic steady state are reached (Wiechert, 2001; Buescher et al., 2015). Metabolic steady state means that the metabolic fluxes as well as the extracellular and intracellular metabolite concentrations are constant. During *in vitro* cultivation of bacteria, metabolic steady-state can be reached through chemostat cultivation (Sauer et al., 1999). Additionally, metabolic quasi-steady state is generally assumed to be reached during exponential growth, as the division rate of cells is at its peak (Buescher et al., 2015). Similarly, at isotopic steady state the isotopic composition of all metabolites remains constant and the fluxes are therefore independent of the metabolite concentrations (Buescher et al., 2015). Under these conditions, the isotopologue composition of a metabolite solely depends on the production fluxes and is independent of its consumption fluxes (Wang et al., 2020). The time-frame for metabolites to reach isotopic steady state after addition of a tracer generally depends on the growth rate of the bacterium and greatly varies for example between soluble cytosolic metabolites and amino acids bound in proteins or sugars bound in the cell wall. While soluble metabolites equilibrate their isotopic composition within minutes after introduction of the ^{13}C -tracers, this can take several hours for metabolites bound in proteins or the cell wall (Buescher et al., 2015). Isotopic steady state can be verified by assessing the isotopic compositions of a metabolite at several time-points after the introduction of the tracer (Beste et al., 2013).

Notably, it can be difficult to achieve either metabolic or isotopic steady-state in pathogen-host situations, as the labeling periods are more likely to be governed by the specific time frames of the infection cycle. This typically determines the periods of bacterial replication and adaptive processes between host and pathogen. In these cases, the time settings in labeling experiments must be specifically adjusted to allow quasi-steady state conditions. In many examples, however, comparison of isotopologue compositions under different conditions or between wild-type and mutant strains can still allow qualitative statements about the functionality of metabolic pathways without strictly assessing the steady state conditions (see also below).

Taking into account these constraints, ^{13}C -patterns in metabolites from the same experiment can be qualitatively or quantitatively compared. In case of isotopic steady state, a retro-biosynthetic approach serves to delineate differential substrate usage and fluxes in the metabolic network. In this approach, borrowing principles from synthetic organic chemistry, the labeling patterns of metabolites (metabolic intermediates) that are not directly measured can be reconstructed from the labeling profiles of their metabolic products on the basis of well-known pathways (Bacher et al., 1998; Bacher and Eisenreich, 2010). As amino acids are directly connected to several central intermediates of the central carbon metabolism, their analysis provides rich insights into the overall metabolism (Fig. 1B). For example, alanine, aspartate and glutamate are produced from pyruvate, oxaloacetate, and 2-oxoglutarate, respectively, *via* simple transamination reactions. Therefore, the excess and isotopologue distribution of these amino acids can be projected to the respective 2-oxo acids, which are also direct intermediates of central carbon metabolism, i.e. the product of glycolysis or the Entner-Doudoroff-pathway (ED pathway) in case of pyruvate, or the citrate cycle in case of oxaloacetate and 2-oxoglutarate.

- (iii) **Analytes useful for isotopologue profiling:** The metabolome comprises thousands of compounds and even restriction to central metabolic compounds still leaves hundreds of molecules for potential analysis. This is practically impossible especially talking into account the low steady-state abundance and instability of some compounds (Buescher et al., 2015). Isotopologue profiling studies therefore mostly focus on highly abundant, stable compounds, such as amino acids (Bacher et al., 1998). As half of the cellular dry weight typically accounts for proteins (Phillips and Milo, 2009), amino acids can be obtained from a relatively low number of bacteria ($>10^7$ bacteria, *ca.* 1 mg dry weight) to allow MS-based isotopologue profiling (Wittmann, 2007). Although more and more LC-MS based applications are developed to analyze increasing amounts of metabolites simultaneously and to capture also low-abundant labile intermediates (Shi et al., 2020), GC-MS based analysis of protein-bound amino acids still remains the gold standard for reliable and robust isotopologue profiling of pathogenic bacteria (Eisenreich et al., 2010; Long and Antoniewicz, 2019).
- (iv) **Choice of the ^{13}C -tracer:** Since the development of isotopic tracers for the study of metabolism, the palette of commercially available ^{13}C -enriched compounds has greatly expanded and almost any potential carbon nutrient to feed into the central carbon metabolism of bacteria can be purchased either in completely ^{13}C -labeled form or ^{13}C -enriched at specific positions. Fully labeled general carbon substrates e.g. $[\text{U-}^{13}\text{C}_6]\text{glucose}$, are ideal for the overall assessment of a metabolic network, since the label from this general source is incorporated into a variety of intermediates of the central carbon metabolism. On the other hand, this approach sometimes does not allow to distinguish between similar metabolic routes. For example, labeling experiments starting from $[\text{U-}^{13}\text{C}_6]\text{glucose}$ do not easily discriminate between glycolysis, the Entner-Doudoroff pathway and the pentose phosphate pathway of glucose degradation. In these cases, additional experiments using selectively ^{13}C -labeled

Fig. 1 Overview of protocols for the isolation and analysis of different kinds of metabolites as well as their connection to the central carbon metabolism. (A) Schematic workflow for the isolation and derivatization of different classes of metabolites. For detailed experimental procedures refer to the main text. (B) Overview of the central carbon metabolism of a model bacterium. Metabolites that can be analyzed by GC-MS are shown in boxes. The color indicates the experimental protocol necessary for the respective compound.

tracers should be performed (Feng et al., 2012). For example, using [1,2-¹³C₂]glucose allows to distinguish between glycolysis and the ED pathway by comparing the label distribution at positions C1 and C2 in alanine as a reporter for pyruvate, the end-product of both glucose-degrading pathways (Fig. 2). A perfect tracer is often hard to choose *ab initio*, often rendering tracer experiments an iterative process (Antoniewicz, 2013). Additionally, different parts of the metabolism often require different tracers for a concise analysis as for example in the case of a bipartite metabolism of pathogens, where [U-¹³C₆]glucose often only allows limited analysis of the tricarboxylic acid (TCA) cycle activity (see below).

Fig. 2 Metabolization of $[1,2-^{13}\text{C}_2]$ glucose to pyruvate via glycolysis or the Entner-Doudoroff pathway. Isotopologue profiling of cells cultivated with $[1,2-^{13}\text{C}_2]$ glucose allows to identify the pathway for glucose degradation. While glycolysis produces $[2,3-^{13}\text{C}_2]$ pyruvate (green), the ED pathway yields $[1,2-^{13}\text{C}_2]$ pyruvate (red). Subsequently, analysis of different mass fragments in alanine, which is derived from pyruvate through deamination, allows to distinguish both pathways. P indicates a phosphate group (Eylert et al., 2010).

- (v) **Cultivation:** In terms of defining appropriate cultivation conditions for a labeling experiment, choice of the medium and duration of the labeling period are crucial. Minimal media or, more generally, chemically defined media allow an optimal control of the amount of tracer to be supplied. Moreover, these conditions are qualified to perform rigorous ^{13}C -metabolic flux analysis in which absolute carbon fluxes from the ^{13}C -tracer to any metabolic product can be determined. For examples, see elegant studies with *Mycobacterium tuberculosis* (*M. tuberculosis*) and *Pseudomonas aeruginosa* (*P. aeruginosa*) (Beste et al., 2013; Lassek et al., 2016; Dolan et al., 2020). However, often pathogens, especially intracellular ones, only show slow growth in minimized media. Therefore, these artificial conditions barely reflect the actual environments during infections. Capitalizing on this aspect, labeling experiments with a pathogen should always consider the chosen experimental conditions to interpret the resulting data in terms of their relevance for actual infections. If isotopic and metabolic steady state cannot be guaranteed for work under the complex medicinally relevant conditions, information can still be gained from these studies by e.g. comparative labeling experiments with mutant strains and appropriate controls. During intracellular growth of pathogens, the time scale of the labeling experiment is often governed by the infection cycle. For example, if lysis of the host cell occurs at a certain time point, the experiment should be stopped earlier to avoid corruption of the labeling data through consumption of the labeled substrate by the released extracellular bacteria. In other cases, the duration of infection must be prolonged to increase the number of bacteria for analysis (Kern et al., 2016). This can also be achieved by high values of the initial multiplicity of infection (MOI) in case of studies with intracellular bacteria (Schunder et al., 2014).
- (vi) **Harvest:** After cultivation in liquid media, the bacteria are typically harvested by rapid centrifugation. The supernatant obtained after cell harvest should also be kept, as the analysis of the residual tracer or secreted compounds in the medium could provide additional information. There is variety of harvest protocols available (Winder et al., 2008; Tambellini et al., 2013), but in general all steps should be as fast as possible and should be performed at low temperatures (4°C). A minimal number of washing steps should be performed after harvest, to get rid of the residual tracer or other medium components interfering with the isotopologue analysis. Washing-solutions without any organic molecules such as phosphate-buffered saline (PBS) or saline are preferred (Wittmann et al., 2004).

When studying intracellular bacteria grown in their respective host cells, an additional separation step is necessary to isolate the bacteria from their hosts. In general, this can be achieved by lysis of the infected host cell and subsequent centrifugation steps. Thereby, cell debris of the host cell with eventually adhered bacteria is collected in the pellet. The supernatant contains the majority of bacteria as well as dissolved molecules from the host cytosol including host proteins. Another centrifugation step of the later fraction allows to separate intact bacterial cells (pellet) from the dissolved host molecules (supernatant) (Schunder et al., 2014; Mehlitz et al., 2017). The quality of the separation steps should be validated by appropriate Western Blot analyses of the respective fractions. After harvest, samples should generally be stored at -80°C until further analysis.

(vii) **Sample workup:** Before isotope analysis, the cell material should be dried *via* lyophilization. As shown in Fig. 1A, different kind of metabolites require different extraction procedures and subsequent chemical derivatization to determine the isotopologue profiles by GC-MS analysis. Depending on the available amount of cell material, all protocols can be performed in parallel. After extraction of soluble metabolites, the remaining pellet of cell debris can be subjected to hydrolysis (see below). Typical protocols are given in the following sections:

- For the analysis of free low-molecular compounds (i.e., cytosolic metabolites), >5 mg of the dried cell pellet is subjected to mechanical disruption in methanol. To this aim, the cellular material is suspended in 1 mL of cold methanol (4 °C) or other solvents and mixed with 750 mg of glass beads (ϕ 0.25–0.5 mm). Disruption is typically performed using a ribolyser system (1×20 s at 4.0 m s^{-1} , 3×20 s at 6.5 m s^{-1}). For extraction of metabolites, methanol is a good compromise, as it dissolves a wide range of metabolites, aids cell disruption, precipitates most bacterial proteins, and can be easily removed due to its volatility (Ser et al., 2015). To separate the soluble metabolites in the supernatant from cell debris and precipitates, the tubes are centrifuged (7000 rpm, 10 min, 4 °C). The clear supernatant is then carefully transferred to a 1.5 mL GC-MS vial and afterwards dried using a stream of nitrogen at room temperature, which takes about 40 min. The derivatization procedures in the next step differs between analysis of sugars or organic acids.
- For analysis of soluble sugars, namely glucose, galactose and fructose, 100 μL of a freshly prepared solution of methoxyamine hydrochloride in anhydrous pyridine (10 mg/mL) is added to the dried residue. The sample is incubated at 30 °C for 90 min. Subsequently pyridine is removed, as it would hamper the next derivatization step, by drying the sample under a stream of nitrogen at room temperature for several minutes. Afterwards, 100 μL of *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) is added to the dried residue and the sample is incubated at 40 °C for 45 min.
- For analysis of soluble organic acids, amino acids and other low molecular-weight metabolites, 50 μL of *N*-methyl-*N*-*tert*-butyldimethylsilyltrifluoroacetamide (MTBSTFA) together with 50 μL of anhydrous acetonitrile are added to the dried residue and derivatization is performed at 70 °C for 60 min, producing *tert*-butyldimethylsilyl (TBDMS) derivatives of the respective compounds.
- For analysis of protein-bound amino acids and eventually of 3-hydroxybutyrate (3-HB) from the poly-hydroxybutyrate fraction (PHB), >1 mg of the dried cell pellet is subjected to acidic hydrolysis in 6 M HCl at 105 °C for 15 h. Cysteine and tryptophan are destroyed during acid hydrolysis. Asparagine and glutamine are deamidated to afford aspartate and glutamate, respectively, during this procedure (Dauner and Sauer, 2000). After hydrolysis, the solution is cooled down to about 70 °C and dried under a stream of nitrogen at 70 °C, which takes about 30–45 min. The dried residue is then resolubilized in 200 μL of 50% acetic acid (aqueous) by vortexing for 10 s or treating the sample in an ultrasonic bath for 2 min after addition of the acetic acid. At the same time, a small column is prepared to perform cation-exchange chromatography. For example, the lower quarter of a 1 mL pipette tip can be filled with glass wool. 200 μL of the column material (Dowex 50 W X8, 7×10 mm, 200–400 mesh, 34–74 μm , H^+ -form) in the form of an aqueous suspension is then put on top of the wool. Afterwards, the column material is washed with 1 mL of 70% MeOH in H_2O and 1 mL of H_2O . Then, the 200 μL sample (see above) is carefully put onto the column, which is first developed by 2 mL of H_2O (bidest). The eluate is collected and contains uncharged or negatively charged molecules (such as 3-hydroxybutyrate or fatty acids). To collect the positively charged metabolites, e.g. amino acids from the proteins or diaminopimelate (DAP) from the cell wall, the column is developed with 1 mL of 4 M ammonia solution (aqueous). For further analysis, both eluates are dried using a stream of nitrogen at 70 °C. These dried eluates can be stored for several months at room temperature (Zamboni et al., 2009). The residue of the aqueous fraction is treated with 100 μL of MSTFA for 90 min at 40 °C while shaking (110 rpm) to form e.g. the trimethylsilyl (TMS)-derivative of 3-HB. The dried residue of the alkaline fraction is treated with 50 μL of MTBSTFA and 50 μL of anhydrous acetonitrile for 30 min at 70 °C to produce TBDMS derivatives of amino acids and DAP from the proteins or cell wall, respectively (Dauner and Sauer, 2000; Eylert et al., 2008; You et al., 2012).
- For the analysis of other cell-wall components, such as muramic acid and glucosamine, >5 mg of the dried cell pellet is subjected to acidic hydrolysis in 6 M HCl at 105 °C for 15 h. Afterwards, the solution is centrifuged (7000 rpm, 10 min) and the clear supernatant is dried under a stream of nitrogen at 70 °C. 100 μL of hexamethyldisilazane (HMDS) are added to the dried residue and derivatization is performed at 120 °C for 3 h.
- For the analysis of bound glucose, mannose and galactose, >3 mg of the dried cell pellet is subjected to acidic hydrolysis in 500 μL of 3 M methanolic HCl for 15 h at 80 °C. The solution is then centrifuged (7000 rpm, 10 min) and the supernatant is transferred to a 4.5 mL GC-MS vial and dried under a stream of nitrogen at 70 °C. Afterwards, 1 mL of a 5:95 (v/v) mixture of H_2SO_4 (conc.) and acetone is added to the dried residue. This mixture is incubated for 1 h at room temperature. Subsequently, the reaction mixture is neutralized by addition of 800 μL of saturated NaHCO_3 solution and 800 μL of saturated NaCl solution. For isolation of sugars, the mixture is extracted three times with 1.5 mL ethylacetate. The organic phases are combined and dried under a stream of nitrogen at room temperature. For derivatization, 100 μL of acetic acid anhydride and 100 μL of anhydrous ethylacetate are added to the dried residue and the mixture is incubated for 16 h at 60 °C. Afterwards, the mixture is brought to dryness using a stream of nitrogen at room temperature. Finally, the sample is dissolved in 100 μL of anhydrous ethylacetate for GC-MS analysis.

(viii) **GC-MS parameters for isotopologue analysis:** Since GC-MS is most frequently used for isotopologue profiling of pathogenic bacteria, we here focus on a typical setting using electron ionization with a quadrupole detector of the mass spectrometer. This

Table 1 GC-MS parameters for the analysis of different classes of metabolites.

	<i>Mur/GlcN</i>	<i>3-HB</i>	<i>Amino acids/DAP</i>	<i>Cytosolic metabolites</i>	<i>Sugars</i>
Temperature program	70 °C (5 min) (5 °C/min)→ 310 °C (1 min)	70 °C (3 min) (10 °C/min)→ 150 °C (50 °C/min)→ 280 °C (2 min)	150 °C (3 min) (7 °C/min)→ 280 °C (3 min)	100 °C (2 min) (3 °C/min)→ 234 °C (1 °C/min)→ 237 °C (3 °C/min)→ 260 °C (10 °C/min)-> 260 °C (2 min)	150 °C (3 min) (10 °C/min)→ 220 °C (50 °C/min)→ 280 °C (3 min)

standard instrumentation also turned out to allow the robust identification and quantification of isotopologues. Moreover, a nonpolar DB-5 column, i.e. 5%-phenyl-methylpolysiloxane, is appropriate for the separation of silyl-derivatives of polar compounds (Wittmann, 2007). The injection volume should be adjusted to achieve an ideal compromise between signal intensity and reproducible signals. When the signal is too low, interference of noise with the mass spectrum can cause high deviations within technical replicates. When the signal is too high, the detector is shut down in the worst case and additionally the intensity of the most abundant isotopologue decreases with higher signal intensities (Antoniewicz et al., 2007), most likely leading to underestimation of the $M + 0$ isotopologue (Dauner and Sauer, 2000). Generally, measurements to analyze the isotopologue compositions of metabolites are performed using selected ion monitoring (SIM) to increase sensitivity and mass resolution, as well as to reduce noise. For analysis of a specific fragment, the masses from $M - 1$ to $M + X + 4$ should be measured, where M is the mass of the fragment containing only ^{12}C and X is the number of carbons in the respective metabolite (Buescher et al., 2015). Measurements should be performed at least in triplicates for each biological sample. Within these technical replicates, the error should be < 1 mol% to ensure reproducible results (Zamboni et al., 2009). Table 1 gives an overview on appropriate GC-MS parameters for the isotopologue analysis of different classes of metabolites.

- (ix) **Methods required to determine the ^{13}C -excess in metabolites by GC-MS analysis:** For data analysis, the mass traces for each metabolite in the chromatogram are extracted (Fig. 3A). While integrating the respective signal in the chromatogram, it should be noted that high enrichment can shift the retention time forwards. This effect is neglectable for most metabolites but must be taken into account when for example fully labeled long chain fatty acids are analyzed (Dauner and Sauer, 2000). The mass trace extracted from a respective GC-signal is compared to the mass trace from the same compound at natural ^{13}C -abundance (Fig. 3B), which has been acquired using a sample obtained from a reference compound. The differences in the isotopologue composition between reference and labeled sample (Fig. 3C, colored bars) are then corrected for the natural abundance of ^{13}C to reveal the actual excess of ^{13}C -isotopologues (Fig. 3D, colored bar) by numerical methods (Lee et al., 1991; Wittmann and Heinzle, 1999; Ahmed et al., 2014). To now calculate the overall ^{13}C -excess of the respective metabolite (Fig. 3D, black bar), which is also referred to as the summed fractional labeling (Wittmann, 2007), the excess of each isotopologue is scaled on the basis of the respective number of ^{13}C -atoms in the isotopologue under study. The ^{13}C -excess, which is specified in mol%, displays the percentage of ^{13}C in the respective molecule above natural abundance (Lee et al., 1991). Therefore, ^{13}C -excess calculation of a molecule should be done with a mass fragment containing the whole carbon skeleton of the molecule. For TBDMS-derivatives, the intense $[\text{M}-57]^+$ -fragment having lost a *tert*-butyl group from the silyl moiety is generally used, while for TMS-derivatives, the calculation relies on the intense $[\text{M}-15]^+$ -fragment having lost a methyl group from the silyl moiety (Wittmann et al., 2002). Due to experimental errors and technical uncertainties, molecules with a ^{13}C -excess < 0.5 mol% are not considered to be significantly enriched (Antoniewicz et al., 2007). The obtained enrichments can then be correlated to the functional metabolic processes (Fig. 3E). This procedure is illustrated by specific examples in the following section.

Examples for isotopologue profiling studies of bacterial pathogens

As mentioned above, the relationship between virulence and metabolism in pathogens becomes more and more apparent. Using the incorporation of stable isotope labeled metabolites, in the context of pathogens referred to as isotopologue profiling, significant progress has been made in the understanding of variety of pathogens, which will be shown by some examples in the following.

Fig. 3 Schematic data evaluation for labeling experiments. (A) GC-chromatogram of amino acids isolated from cellular proteins after hydrolysis. (B) Mass spectrum of the [M-57]⁺-fragment of the *tert*-butylidimethylsilyl-derivate of glutamate at natural abundance. (C) Mass spectrum of the [M-57]⁺-fragment of the *tert*-butylidimethylsilyl-derivate of glutamate showing ¹³C-enrichment. Colored bars refer to the indicated isotopologues. (D) Isotopologue distribution (colored bars) calculated from the mass spectrum. Percentage values indicate the abundance of the respective isotopologue. The black bar depicts the overall ¹³C-excess, calculated as the weighted abundance of the individual isotopologues. (E) Connection between labeling data and metabolic incorporation of the tracer. Colored circles show ¹³C-atoms, while empty circles display ¹²C-atoms.

Listeria monocytogenes

Extensive work was done on the metabolism of *Listeria monocytogenes* (*L. monocytogenes*) using ¹³C-labeling experiments under *in vitro* as well as *in vivo* conditions. Initial experiments, where ¹³C-patterns in protein-bound amino acids were determined by NMR after growth on [U-¹³C₆]glucose in broth already revealed differences in the metabolic capabilities as compared to metabolic models predicted by the genome composition alone (Eisenreich et al., 2006). While the pathways for production of serine and isoleucine were annotated in the *L. monocytogenes* genome (Buchrieser et al., 2003), they were found to be inactive under the

respective experimental conditions of the ^{13}C -experiment. The isotopologue profiles in amino acids clearly revealed the incomplete TCA cycle and the importance of pyruvate carboxylation to oxaloacetate as an essential reaction to afford this precursor for e.g. aspartate or mDAP (Eisenreich et al., 2006).

After having established the functional metabolic pathways of *L. monocytogenes* growing in broth, experiments with *L. monocytogenes* growing inside transformed macrophages (such as J774A.1) and primary murine bone marrow-derived macrophages (BMM) were performed starting from various tracers (e.g., $[\text{U-}^{13}\text{C}_6]\text{glucose}$, $[\text{U-}^{13}\text{C}_3]\text{serine}$, $[\text{U-}^{13}\text{C}_3]\text{glycerol}$). Careful GC-MS analysis of the isotopologue profiles in amino acids from the bacterial and the host fraction elucidated differential substrate usages and metabolic routes of *L. monocytogenes* under intracellular conditions (Eylert et al., 2008; Gillmaier et al., 2012; Grubmüller et al., 2014). As observed for many intracellular pathogens, *de novo* synthesis of most amino acids was avoided and compensated by the uptake of these compounds from the host cell during intracellular growth (Eisenreich et al., 2017). Noteworthy, especially alanine, aspartate, and glutamate, were made by the intracellular bacteria. Using mutants, defective in glucose phosphate uptake, verified synthesis of these amino acids using the supplied labeled glucose (Eylert et al., 2008). The incomplete TCA cycle in *L. monocytogenes* led to a pronounced $M + 3$ isotopologue in bacterial aspartate (formed from $M + 3$ oxaloacetate *via* carboxylation of $^{13}\text{C}_3$ -pyruvate) as compared to $M + 2$ aspartate from the host (formed from $M + 2$ oxaloacetate *via* the TCA cycle starting from $^{13}\text{C}_2$ -acetyl-CoA), when metabolizing $[\text{U-}^{13}\text{C}_6]\text{glucose}$ (Fig. 4) (Gillmaier et al., 2012). The careful inspection of the labeling patterns in multiple metabolites and further labeling experiments revealed a bipartite metabolic network for intracellularly growing *L. monocytogenes* (Fig. 6). In this topology, glycerol is a preferential carbon source for energy supply and catabolism in general, but not for gluconeogenesis, while glucose 6-phosphate supports anabolism, i.e. synthesis of cell wall carbohydrates and RNA/DNA (Grubmüller et al., 2014). Together, these data provided first insights into the functional metabolic network of an intracellular pathogen, which is highly adapted to its intracellular niche. Comparing the results obtained from experiments with primary and transformed macrophages as host cells for *L. monocytogenes* infection, it turned out that the bacterial pathways were quite similar if not identical in the different host cells. However, primary macrophages showed a distinct upregulation of host glycolysis due to the listerial infection (Gillmaier et al., 2012).

Legionella pneumophila

To understand the functional metabolism of *Legionella pneumophila* (*L. pneumophila*), the bacteria were grown in broth containing $[\text{U-}^{13}\text{C}_6]\text{glucose}$, $[1,2\text{-}^{13}\text{C}_2]\text{glucose}$ or $[\text{U-}^{13}\text{C}_3]\text{serine}$. Serine was efficiently metabolized by *L. pneumophila* as the major carbon source under these conditions, while glucose was used as an additional minor nutrient. Using $[1,2\text{-}^{13}\text{C}_2]\text{glucose}$ as a precursor, it was possible to distinguish between glycolysis and the ED pathway (Fig. 2), which is the preferred way for glucose utilization in *L. pneumophila*, even though both pathways are completely annotated in the genome. Additionally, analysis of 3-hydroxybutyrate obtained from the hydrolysate of PHB, revealed efficient glucose metabolism into this macromolecular storage compound (Eylert et al., 2010). These observations were further refined using growth phase dependent labeling experiments during *in vitro* cultivation. Again, using $[\text{U-}^{13}\text{C}_6]\text{glucose}$ or $[\text{U-}^{13}\text{C}_3]\text{serine}$, which were added at the beginning of the early exponential,

Fig. 4 Utilization of $[\text{U-}^{13}\text{C}_6]\text{glucose}$ by *L. monocytogenes* and its macrophagic host cell during infection produces different isotopologue profiles in pathogen- and host-derived aspartate. *L. monocytogenes* and the host cell both initially produce $M + 3$ pyruvate from fully labeled glucose. The incomplete TCA cycle in *L. monocytogenes* only allows further conversion to oxaloacetate through carboxylation, hence producing $M + 3$ aspartate (red). In contrast, the eukaryotic host cell uses a complete TCA cycle thereby producing $M + 2$ aspartate (green). AcCoA, acetyl-CoA; 2-OG, 2-oxoglutarate; OAA, oxaloacetate (Gillmaier et al., 2012).

post-exponential or stationary phase, respectively, a growth-phase dependent metabolization of these compounds was observed (Gillmaier et al., 2016). While serine was predominantly used during the early phase of exponential growth *via* the TCA cycle, glucose mainly served for PHB synthesis during the later stages (Gillmaier et al., 2016; Heuner and Eisenreich, 2016). Further experiments expanded the palette of carbon substrates used by *L. pneumophila*, as [U-¹³C₃]glycerol was also metabolized *in vitro* as well as *in vivo*. In contrast to *L. monocytogenes*, glycerol was mainly used for anabolic metabolism *via* gluconeogenesis in *L. pneumophila*. Still, as serine is mainly metabolized through the TCA cycle, this again supported a bipartite-like topology of *L. pneumophila* metabolism (Fig. 6) (Häuslein et al., 2016). Further isotopologue profiling experiments with a carbon storage regulator A-mutant (CsrA) of *L. pneumophila* showed the role of this global regulator in mediating the switch from amino acid metabolism during exponential growth to glycerolipid metabolism at later growth phases, when amino acids become limited. Using [1,2,3,4-¹³C₄]palmitate as a precursor, the role of fatty acids as additional carbon substrates was indeed corroborated again by the ¹³C-technology (Häuslein et al., 2017b).

Amoebae present the natural hosts for *L. pneumophila*, but the mechanisms of infection are thought to be similar to macrophages (Swart et al., 2018). Therefore, experiments with *Acanthamoeba castellanii* (*A. castellanii*), which were grown in the presence of [U-¹³C₆]glucose or [U-¹³C₃]serine before infection, were carried out to investigate the metabolic capabilities of *L. pneumophila* *in vivo*. Comparing the isotopologue profiles of amino acids from the bacterial fraction and the host proteins, it turned out that almost no *de novo* synthesis from the respective ¹³C-substrates had occurred by the intracellular bacteria. Rather, with the exception of some minor fraction of *de novo* synthesized alanine, aspartate and glutamate, amino acids were taken up from the host and directly incorporated into the bacterial proteins (Schunder et al., 2014). In another set of labeling experiments using [U-¹³C₆]glucose or [U-¹³C₃]serine as tracers, the metabolism of *L. pneumophila* growing within *A. castellanii* was studied during different time intervals, i.e. 0–17 h, 17–25 h, or 25–27 h post infection (Kunze et al., 2021). Comparative GC-MS analysis of the ¹³C-patterns again revealed that the intracellular bacteria efficiently utilized amino acids from the amoebae for the synthesis of their own proteins during the whole infection cycle. However, the data also showed that, for *de novo* synthesis of alanine, aspartate and glutamate, serine was utilized *via* the TCA cycle at increasing rates during the post-exponential phase of growth. In contrast, glucose was used during the whole infection cycle and not only during the late growth phase. This was surprising since earlier *in vitro* experiments suggested glucose utilization during the late growth phase only (see above). It is tempting to speculate that glucose availability could serve as a signal for the start of replication of *L. pneumophila* when thriving within host cells.

Mycobacteria

Mycobacteria and especially *M. tuberculosis* have also been extensively studied using isotopologue profiling. During *in vitro* cultivation, the general metabolic capabilities of this pathogen were assessed using [U-¹³C₆]glucose, [U-¹³C₂]acetate or [U-¹³C₃]glycerol as tracers. Surprisingly, *M. tuberculosis* showed co-utilization of these substrates, which accelerated growth in comparison to the theoretical growth rates on single substrates (Fig. 6) (De Carvalho et al., 2010). Subsequently, rigorous ¹³C-metabolic flux analysis (MFA) was performed in chemostat cultures. This revealed the activity and importance of a so-called GAS-pathway (glyoxylate shunt-anaplerosis-succinyl-CoA synthetase) for *M. tuberculosis* growth (Fig. 5). Herein, acetate is the main substrate and utilization proceeds through the glyoxylate shunt. Oxaloacetate is decarboxylated to allow for gluconeogenesis, while succinyl-CoA synthetase compensates for the interrupted TCA cycle (Beste et al., 2011). ¹³C-MFA was then performed studying *M. tuberculosis* during growth in macrophages (Beste et al., 2013). A mixture of amino acids as well as acetate were taken up from the host cell and experiments with ¹³C-bicarbonate demonstrated active carboxylation reactions during infection. Additionally, the results suggested the usage of a C3-substrate as an additional carbon source for intracellular *M. tuberculosis*. On this basis, lactate seems to provide an additional carbon substrate during intracellular growth (Billig et al., 2017) besides lipids as the main substrates (Schnappinger et al., 2003). As lactate is produced in excess in activated macrophages, the finding of lactate usage probably reflects metabolic adaption of the intracellular pathogens (Billig et al., 2017).

It is also interesting to note the general metabolic flexibility and adaption mechanisms of mycobacteria. For example, studies using *M. leprae* within Schwann cells revealed the active usage of host glucose by the pathogen to synthesize amino acids (Borah et al., 2019). While *M. tuberculosis* exploits the PEP carboxykinase reaction for anaplerosis of acetate, this reaction is crucial for glucose catabolism in *M. leprae*.

Other intracellular pathogens

Labeling studies with *Chlamydia trachomatis* (*C. trachomatis*) in HeLa cells revealed that the obligate intracellular pathogen incorporated [U-¹³C₆]glucose at high rates into chlamydial lipopolysaccharide probably *via* glucose 6-phosphate from the host cell (Mehlitz et al., 2017). Bacterial alanine, aspartate, and glutamate were biosynthesized *de novo* using dicarboxylates from the host cell, such as malate or 2-oxoglutarate (from host glutamine). Indeed, the importance of host glutamine for *C. trachomatis* replication in primary human umbilical vein endothelial cells (HUVEC) was confirmed in more recent studies, showing that the infection leads to upregulation of glutamine import and a glutaminase (Rajeev et al., 2020). Together, the data again reflect co-substrate usage in a bipartite metabolic network with host cell-provided G6P for cell wall biosynthesis, and, to some extent, one or more host cell-derived dicarboxylates, i.e. malate and/or glutamine-derived 2-oxoglutarate, feeding the partial TCA cycle of the bacteria (Fig. 6). The latter flux could also support the biosynthesis of mDAP required for the formation of chlamydial peptidoglycan.

Fig. 5 GAS-pathway (glyoxylate shunt-anaplerosis-succinyl-CoA synthetase) observed in *M. tuberculosis*. Anaplerotic reactions are marked in red. Reactions of the glyoxylate shunt are marked in green, while reactions from the TCA cycle as well as succinyl-CoA synthetase are indicated in blue. Adapted from Beste DJ, Bonde B, Hawkins N, Ward JL, Beale MH, Noack S, Noh K, Kruger NJ, Ratcliffe RG, and McFadden J (2011) ^{13}C metabolic flux analysis identifies an unusual route for pyruvate dissimilation in *mycobacteria* which requires isocitrate lyase and carbon dioxide fixation. *PLoS Pathogens* 7: e1002091.

For *Francisella holarctica tularensis* (*F. tularensis*), ^{13}C -isotopologue profiling allowed to elucidate the central metabolic network through various ^{13}C -tracers. Additionally, comparison of strains varying in virulence revealed differences in the metabolic profiles especially in terms of the extent of gluconeogenesis from glycerol. All strains displayed a bipartite metabolic network, where amino acids are mainly used for energy generation through the TCA cycle, while glucose and glycerol are used for gluconeogenesis and cell wall synthesis (Chen et al., 2017).

An elegant study by Kentner et al. combined proteomics, metabolomics and ^{13}C -profiling with $[\text{U-}^{13}\text{C}_6]$ glucose or $[\text{U-}^{13}\text{C}_3]$ pyruvate to show that intracellular *Shigella flexneri* (*S. flexneri*) utilizes pyruvate produced through host glycolysis for its own metabolism (Fig. 6). Here, pyruvate is metabolized to acetate by the pathogen, which is then excreted *via* the host cell. This nutrient scavenging by *S. flexneri* allows fast replication inside the host, with generation times comparable to cultivation in broth under ideal conditions (Kentner et al., 2014).

Coxiella burnetii, another obligate intracellular pathogen, could be grown in axenic medium in 2010 for the first time. Under these conditions, experiments with ^{13}C -glucose, ^{13}C -serine or ^{13}C -glycerol confirmed a bipartite-type metabolism, where serine mainly contributes to energy generation through the TCA cycle, while glycerol enters gluconeogenesis (Fig. 6). Analysis of the activity of metabolic modules was facilitated by the analysis of representative intermediates, e.g. alanine for glycolysis, aspartate for the TCA cycle, diaminopimelate and glucosamine for cell wall synthesis (Häuslein et al., 2017a).

Experiments with *Salmonella enterica* growing inside CaCo-2 cells, revealed glucose as a nutrient source during intracellular replication. This finding was corroborated by labeling experiments with mutants deficient in glucose uptake (Götz et al., 2010).

Extracellular pathogens

Similar to intracellular pathogens, isotopologue profiling has also been used to characterize the central carbon metabolism of extracellular pathogens, such as *Streptococcus pneumoniae*. Here, experiments with $[\text{U-}^{13}\text{C}_6]$ glucose and $[\text{U-}^{13}\text{C}_2]$ glycine revealed that the Embden-Meyerhof-Parnas (EMP) pathway is the main glycolytic pathway. Further, the ^{13}C -patterns of serine, alanine and

Fig. 6 Examples of bipartite metabolism observed in various intracellular bacteria. Blue and red arrows indicate the anabolic metabolism, which is responsible for the production of precursors for e.g. cell wall components and ribonucleotides. Green arrows indicate catabolism that mainly produces energy. Separation of these metabolic modules is indicated by the dotted lines. Main substrates identified by isotopologue profiling are indicated by the boxes. *Glucose-P*, glucose-6-phosphate; *GAP*, glyceraldehyde-3-phosphate; *OAA*, oxaloacetate; *2-OG*, 2-oxoglutarate; *PHB*, polyhydroxybutyrate; *acetyl-P*, acetyl-phosphate (De Carvalho et al., 2010; Beste et al., 2011; Grubmüller et al., 2014; Kentner et al., 2014; Häuslein et al., 2016, 2017a,b; Mehltz et al., 2017; Rajeev et al., 2020).

glycine revealed that serine is not produced from 3-phosphoglycerate but exclusively from glycine through the addition of formate. Interestingly, mutants with defects related to virulence showed no differences in the core metabolic features (Härtel et al., 2012). Similarly, metabolic capabilities could be assessed by ^{13}C -labeling studies in *Streptococcus suis* (Willenborg et al., 2015). The data unequivocally reflected that the EMP pathway was the main catabolic route for glucose utilization. Further, the PEP carboxylase reaction plays a central role in the metabolism of *S. suis* to produce oxaloacetate, because other anaplerotic reactions are absent and the TCA cycle is incomplete.

For *Staphylococcus aureus*, the metabolic phenotype of the wild-type strain was compared to a small colony-variant, which is related to persistent infections. Experiments with $[\text{U-}^{13}\text{C}_6]\text{glucose}$ together with transcriptome analysis showed reduced ^{13}C -excess in TCA cycle related amino acids due to a reduced aconitase activity in the small-colony variant (Kriegeskorte et al., 2014).

In *Campylobacter jejuni*, isotopologue profiling was combined with a transposon insertion library to evaluate metabolic requirements for the colonization in mice. This revealed a metabolic network with limited capabilities and low redundancy as well as the importance for the uptake of serine and aromatic amino acids during infection (Gao et al., 2017).

In *P. aeruginosa* using $[1\text{-}^{13}\text{C}]\text{glucose}$, the ED pathway was identified as the main route for glucose catabolism (Lassek et al., 2016). Further studies during growth on labeled glycerol or acetate revealed a bipartite metabolic network, mentioned above for intracellular pathogens. While glycerol preferentially enters gluconeogenesis, acetate is mainly metabolized in the TCA cycle (Dolan et al., 2020). Another study reported metabolic differences between clinical isolates of *P. aeruginosa* suggesting adaption to the respective niche in the host. Either, TCA cycle and ED pathway activities were high, while PPP activity was low or vice versa pointing to different extents of biofilm formation in the isolates or adaption to different oxygen levels (Opperman and Shachar-Hill, 2016).

Another study compared usage of ^{13}C -glucose of enterohemorrhagic *E. coli* in different media, imitating growth in the ileum or the colon respectively. Both conditions produced different metabolic phenotypes as well as different expression of virulence factors, suggesting a close connection between metabolism governed by the respective ecological niche and virulence (Polzin et al., 2013).

Plant pathogens

Although to a much smaller extent than for human pathogens, the metabolism of plant pathogens has also been under investigation using isotopically labeled metabolic precursors. In *Xanthomonas campestris*, the pathways for amino acid synthesis were identified using $[1\text{-}^{13}\text{C}]\text{glucose}$. This also allowed for the clarification of ambiguities in the synthesis of alanine, glycine, and isoleucine, which arose through redundancies in a putative metabolic network based on genome annotations (Schatschneider et al., 2011). A similar approach was used for *Xanthomonas oryzae* using labeled xylose or glucose as tracers (Shree and Masakapalli, 2018).

Finally, isotopologue profiling together with genomic analysis in *Ralstonia solanacearum* identified the ED pathway together with the oxidative pentose phosphate pathways as the main glucose degrading pathways (Jyoti et al., 2020).

"In order to pursue chemotherapy successfully we must look for substances which possess a high affinity and high lethal potency in relation to the parasites, but have a low toxicity in relation to the body, so that it becomes possible to kill the parasites without damaging the body to any great extent. We want to hit the parasites as selectively as possible. In other words, we must learn to aim and to aim in a chemical sense. The way to do this is to synthesize by chemical means as many derivatives as possible of relevant substances".

"We may regard the cell quite apart from its familiar morphological aspects, and contemplate its constitution from the purely chemical standpoint. We are obliged to adopt the view, that the protoplasm is equipped with certain atomic groups, whose function especially consists in fixing to themselves food-stuffs, of importance to the cell-life. Adopting the nomenclature of organic chemistry, these groups may be designated side-chains. We may assume that the protoplasm consists of a special executive centre (Leistungs-centrum) in connection with which are nutritive side-chains . . . The relationship of the corresponding groups, i.e., those of the food-stuff, and those of the cell, must be specific. They must be adapted to one another, as, e.g., male and female screw (Pasteur), or as lock and key (E. Fischer)".

Paul Ehrlich (1854–1915).

Introduction

Metabolomics constitutes the analysis of metabolites in a biological sample and its behavior through the biological process in order to establish a specific metabolic flow conduct or fluxomics (Babele and Young, 2020). In this way, the metabolic flow of a normal or pathological biological process is a powerful source of information to evaluate different aspects of the causes of the disease, as well as its natural history and behavior under the established treatment (McCue and McCoy, 2017; Wishart, 2019; Hill et al., 2020). On the other hand, the metabolomic and fluxomic of infectious diseases allows to demonstrate the ways that use pathogenic microorganisms during the infectious process, as well as monitor the success or failure of antimicrobial treatment (Cuperlovic-Culf et al., 2013; Durmuş et al., 2015). Thus, infectious diseases produced by bacteria, viruses, fungi and parasites are one of the greatest causes of mortality in the world (Vos et al., 2020), it what prioritizes implementing new diagnostic techniques that improve detection and help block the transmission of microorganisms between the population (Agrebi and Larbi, 2020). In this order of ideas, the profile behavior of metabolism during infectious disease is a useful approach for the implementation of theranostics impact models, that is to say diagnostic techniques capable of detecting and treating the disease in the same probe, with which it obtaining it of metabolomes and fluxomes of the interaction host-microorganism allow the observation in real time of specific biological parameters with which to establish a predictive model of the clinical response (Kumar et al., 2020; Mussap et al., 2020). In this way the development of predictive health and disease models in infections is the key to establishing a correct customized clinical response based on the metabolomics of the patient (Seyhan and Carini, 2019; Diray-Arce et al., 2020). Thus, the metabolomics of infectious disease constitutes a model of precision medicine (PM) with a high predictive value in diagnosis, treatment and vaccination, due to the integration of biochemical and genetic parameters into a systems biology that allows due monitoring of affected patients (Tebani et al., 2016; Jaiswal et al., 2020). For this reason, the objective of this article is to analyze the applications of metabolomic-fluxomic dyad in infectious diseases as well as their impact on diagnosis, prevention and treatment.

Metabolomic-fluxomic dyad

In this order of ideas, metabolomics describes the various metabolites involved in biological processes, which attached to the fluxomics that integrates this bioinformation to determine the rate of reactions in a biological individual at any stage (Rosato et al., 2018; Volkova et al., 2020). In this way secondary metabolites produced both by the microorganism and the host are fundamental biomarkers to be evaluated by concentration curves at the time of the infectious process (Byers et al., 2019; Du Preez and Luies,

2019). Thus, the infectious metabolome can be addressed by the analysis of the synthesis of the small molecules represented by amino acids, lipids, nucleotides, sugars, hormones and vitamins that may be altered during the disease using the process of analysis of the samples presented in Fig. 1 (Romagnolo and Carvalho, 2021). Likewise, obtaining the principal component analysis (PCA) of the infected patient's sample allows to establish the physiological changes that microorganisms work on the host during infection, equally with the information of these metabolites present in the PCA in correlation with the clinical data can be introduced into a bioinformatic model to obtain the fluxomic of the disease (Zhang and Castelló, 2017; Bhadra and Rousu, 2018; Zhang et al., 2019). Thus, this integrative system approach achieves the obtaining of the Principal Metabolic Flux Mode Analysis (PMFA) (Fig. 2), which is an indicator of the metabolism of the host-pathogen interaction where it is possible to predict the clinical response of the patient against the microbial invasion (Pey and Planes, 2014; Rienksma et al., 2019). But it is important to remember that it should start from which of the different molecules represented in amino acids, lipids, nucleotides, sugars, hormones and vitamins can be physiologically altered and constitute a biomarker of infectious disease (Hwang et al., 2018). In this way the metabolome should offer a correct chemical characterization of the metabolic exchange between the environment and the host during the infectious process, in order to determine the adaptive response of the patient in the face of illness (Fig. 3) (Fernández-García et al., 2018). Likewise, a validation of the biomarker is necessary to establish the sensitivity, specificity, positive predictive value and negative predictive value of the analytes identified by metabolomic-fluxomics analysis (Gowda and Raftery, 2013; Percival et al., 2020).

Fig. 1 Workflow for metabolomic studies.

Fig. 2 Fluxomic data with principal metabolic flux mode analysis.

Fig. 3 Flow of metabolic exchanges between the host and the environment.

Metabolomic analysis of infection

In this order of ideas it is important to emphasize that the pathogenesis of infectious disease and its different phases such as incubation, the prodromal phase, acute disease, recovery and/or chronic disease are those that should influence metabolomic analysis for establish a real prediction of the clinical response (Pacchiarotta et al., 2012; Beale et al., 2019; Bernatchez and McCall, 2020). Likewise, the metabolites released by the microorganism as well as the molecules that make up its structure during the invasion and that can be determined in the different clinical samples are part of the analysis present in the metabolome that can give information on the resolution of the condition (Tang, 2011; Pinu and Villas-Boas, 2017; Pinu et al., 2017). Finally, it is important to correlate both the fluxomic of the host and that of the etiological agent during the infectious disease to obtain a model of biology of systems that describe the pathophysiology and its behavior in a personalized medicine approach (Fig. 4.) (Mardinoglu and Nielsen, 2012; Aon and Cortassa, 2015; Karakitsou et al., 2019). In this way, the evaluation of a physiological pattern of infectious disease was required based on metabolomics, where each stage can be established by the concentration of specific molecules produced by both the host and microorganism; said pattern may be made up of immunomodulatory molecules that can be an estimate of the host response to infection (Vernocchi et al., 2016; Thakur et al., 2019). Among these immunomodulatory molecules there are host defense peptides and cytokines; as well as carbohydrates, lipids and amino acids involved in immune processes (Maizels et al., 2018; Mookherjee et al., 2020). In this order of ideas, the immunity of the host versus the infection is one of the targets of study of a functional metabolomic model capable of giving information with which to restore the parameters of the metabolome and maintain the homeostasis of the affected patient (Belkaid and Harrison, 2017; Torow and Hornef, 2017; Ayres, 2020). Thus, the functional metabolomic analysis of the infectious process aimed at studying the immune response of the host in conjunction with the microbial metabolism should integrate the parameters of glycomics, proteomics, lipidomics in integration with fluxomics (Fig. 5) (Yang, 2016; Poudel et al., 2019). In other words, the obtaining of an infectious disease phenotype should be sought, in this way platforms such as PathoPhenoDB have worked in making important associations in this field of precision medicine (Hoehndorf et al., 2015; Kafkas et al., 2019).

Diseasome a new natural history of the disease

Diseasome is an approximation that makes up a network model of human illness to analyze the interactome between the causal agent and the host (Fig. 6) (Navratil et al., 2011; Khorsand et al., 2020; Silverman et al., 2020). In this way, the assessment of diseasome is capable of integrating biological systems together with the adaptive reaction to the environment and the pathogen in order to determine the factors of the host that are altered and allow the disease to persist (Gluckman et al., 2011; Balloux and van Dorp, 2017). Thus, the diseasome of infection, as well as infectome can find correlations between infectious disease and various comorbidities that predispose it; such as diabetes mellitus, malnutrition and cancer. This is a major breakthrough in personalized and comprehensive disease management (Faner et al., 2015; Satu et al., 2021). In that order of ideas the modeling of infectious diseasome contemplates the evaluation of various parameters among them the protein-protein interactions, transcriptional control networks and signal transduction networks, all integrated into a mathematical model for bioinformatic analysis. In summary, the entire study requires including the following data during infection (Hoehndorf et al., 2015; Lau et al., 2018; Barh et al., 2020):

Fig. 4 Metabolomic analysis of systems medicine.

Fig. 5 Omics cascade for establish an infectious phenotype.

Likewise, the bioinformatic study of infectious disease should be correlated with the clinical variables of it as they are the presentation of symptoms, grades of severity, healing and fatality rates. In order to obtain a real approach of what happens in the host (Keeling and Danon, 2009; Gambhir et al., 2015). But also when trying to implement a bioinformatic approach so robust to be applied in the clinic of infectious diseases, metabolomic should try to respond to diagnostic, treatment, prevention and clinical procedures needs that is what prevents the translation of mathematics to the patient's bed (Kohler et al., 2016; Delhalle et al., 2018).

Metabolomics activity screening

Metabolomics Activity Screening (MAS) is the analysis model that seeks to integrate metabolome with metabolic pathways and systems biology in order to identify metabolites that modulate the functionality of physiological processes (Peng et al., 2015; Guijas et al., 2018). Thus, the metabolites as biomarkers of gene expression and the functionality of the proteins that modulate the phenotype, offer valuable information such as diagnostic and discovery tools of new drugs (Johnson et al., 2016; Rinschen et al., 2019; Davis et al., 2020). In this way, it is necessary to have a list of metabolites to be evaluated to elucidate the altered metabolic pathways during the infectious process, in this case a tentative list consigned in Table 1. can be given (Gebregiworgis and Powers, 2012; Song et al., 2019; Tounta et al., 2021).

Likewise, in the context of the immune response of the host against the infection there are metabolic pathways that can be valued to be correlated with functionality, these routes are included in Table 2 (Mazumdar et al., 2020).

Table 1 Metabolites to be evaluated in Metabolomic Activity Screening models.

<i>Metabolic pathway involved</i>	<i>Metabolite</i>
Glycolysis	β -D-Glucose 6-phosphate, D-fructose 6-phosphate, β -D-fructose 1,6-bisphosphate, D-glyceraldehyde 3-phosphate, dihydroxyacetone phosphate, pyruvic acid, lactic acid
Pentose phosphate pathway	D-Ribose-5-phosphate, D-gluconate-6-phosphate, D-ribulose-5-phosphate, D-gluconic acid
Bioenergetics	NAD ⁺ , NADH, ADP, ATP
Tricarboxylic acid cycle	cis-Aconitic acid, D-threo-isocitric acid, α -ketoglutaric acid, succinyl-CoA, acetyl-CoA, succinic acid, fumaric acid, malic acid, oxaloacetic acid
Nitrogen metabolism	Citrulline, L-ornithine, arginine, arginosuccinic acid, glutamine, glutamic acid
Amino acids	Alanine, arginine, asparagine, aspartic acid, cysteine, glutamine, glutamic acid, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, proline, serine, threonine, tryptophan, tyrosine

Table 2 Metabolites, metabolic pathways and immune system activity.

<i>Metabolic pathway involved</i>	<i>Metabolite</i>	<i>Cell of the immune system</i>
Glycolysis (phagocytosis)	β -D-Glucose 6-phosphate, D-fructose 6-phosphate, β -D-fructose 1,6-bisphosphate, D-glyceraldehyde 3-phosphate, dihydroxyacetone phosphate, pyruvic acid, lactic acid	Neutrophil, macrophages, CD ⁴ lymphocytes, dendritic cells
Pentose phosphate pathway (H ₂ O ₂ production)	D-Ribose-5-phosphate, D-gluconate-6-phosphate, D-ribulose-5-phosphate, D-gluconic acid	Neutrophil, macrophages
Bioenergetics	NAD ⁺ , NADH, ADP, ATP	Macrophages, CD ⁸ lymphocytes

Table 3 Metabolites, metabolic pathways and microorganism.

Metabolic pathway involved	Metabolite	Microorganism
Glycolysis	β -D-Glucose 6-phosphate, D-fructose 6-phosphate, β -D-fructose 1,6-bisphosphate, D-glyceraldehyde 3-phosphate, dihydroxyacetone phosphate, pyruvic acid, lactic acid	Hepatitis B <i>Escherichia coli</i> <i>Klebsiella pneumoniae</i> <i>Pseudomonas aeruginosa</i> <i>Proteus mirabilis</i>
Bioenergetics	NAD ⁺ , NADH, ADP, ATP	Hepatitis B
Tricarboxylic acid cycle	cis-Aconitic acid, D-threo-isocitric acid, α -ketoglutaric acid, succinyl-CoA, acetyl-CoA, succinic acid, fumaric acid, malic acid, oxaloacetic acid	<i>Streptococcus pneumoniae</i> <i>Escherichia coli</i> <i>Plasmodium falciparum</i> <i>Schistosoma mansoni</i> HIV
Nitrogen metabolism	Citrulline, L-ornithine, arginine, arginosuccinic acid, glutamine, glutamic acid	<i>Escherichia coli</i>
Amino acids	Alanine, arginine, asparagine, aspartic acid, cysteine, glutamine, glutamic acid, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, proline, serine, threonine, tryptophan, tyrosine	<i>Escherichia coli</i> Hepatitis B HIV

On the other hand in clinical samples from patients with bacterial, viral, mycotic and parasitic infectious diseases, corresponding metabolites can be identified that can be indicators of acute or chronic condition as included in Table 3. (Pacchiarotta et al., 2012; Voge et al., 2016; Weiner et al., 2018).

Thus, Metabolomic Activity Screening as a strategy in the search for biomarkers should be correlated closely with clinical practice with the aim of obtaining metabolomes that can be analyzed in silico to identify patterns corresponding to the infectious process (Pinu et al., 2019a, 2019b; Bardanzellu and Fanos, 2020; Long et al., 2020). But it is important to emphasize that any metabolomic study requires specific precision devices to be able to obtain metabolomes of clinical samples reproducibly, automate and robust (Bi et al., 2020; Smith et al., 2020).

Metabolomics and mass spectrometry

In this way, gas chromatography coupled to mass spectrometry (GC-MS) it has been employed as a precision equipment for the analysis of urine samples, plasma and detection of Volatile Organic Compound (VOC) excreted in patients with viral and bacterial infections (Sethi et al., 2013; Stevens and Pukala, 2020; Djago et al., 2021). Thus, GC-MS is a robust method of analysis that allows identifying the amount of metabolites depending on the mass in a sample in order to elucidate metabolic pathways of the infectious process that affects the patient (Khodadadi and Pourfarzam, 2020; Nunes et al., 2021). In this order of ideas, with this method, the metabolomic targeted and untargeted strategies can be developed; in the first the amount of metabolites known to detect is less (from 10 to 100), in the second it is sought to quantify as much metabolites as possible from a sample to identify metabolic changes, so that the strategy untargeted is very employed in studies about metabolomic in infectious diseases (Schrimpe-Rutledge et al., 2016; Trivedi et al., 2017; Jiang et al., 2020). Thus, targeted Metabolomics has been used to assess changes in specific metabolites before, during and after antimicrobial treatment in order to develop predictive models of disease (Zurfluh et al., 2018; Vrieling et al., 2019). Likewise, untargeted metabolomics can also be performed by liquid chromatography on an LC-MS model to identify microorganisms and their pathogens forms (Franco-Duarte et al., 2019; Depke et al., 2020). Equally (High Performance Liquid Chromatography) HPLC-MS has been evaluated to quantify the metabolites present in plasma samples from patients that present infectious processes, it also allows establishing a clinical response to antimicrobial treatment in a targeted model (El-Najjar et al., 2017; Chen et al., 2020). On the other hand, additional methods have been coupled to mass spectrometry such as Matrix Assisted Laser Desorption Ionization-Time of Flight (MALDI-TOF) and Electrospray Ionization (ESI) in order to increase the sensitivity and specificity of metabolomic analysis, as well as the identification of pathogenic microorganisms present in clinical samples (Chong et al., 2018; Leopold et al., 2018; Ščupáková et al., 2020). But it is important in a model of untargeted metabolomics elucidate the structure of the quantified molecule in order to specifically determine the possible biomarker (Zhang et al., 2020).

Nuclear magnetic resonance (NMR) spectroscopy

Nuclear magnetic resonance is a method with a high utility in the structural elucidation of molecules in an untargeted metabolomic model (Emwas et al., 2019; Crook and Powers, 2020). Thus, in this order of ideas NMR has been used to detect biomarkers in tuberculosis, dengue and hepatitis, as well as to differentiate between bacterial and viral infections (Gebregiworgis and Powers,

2012; El-Bacha et al., 2016; Meoni et al., 2019; Grauslys et al., 2020). In this order NMR is an exploratory technique that allows identifying new metabolites in clinical samples as well as evaluating the concentration of specific compounds, which is why a robust method is considered to be implemented in research to determine fluxomics (Sussulini, 2017; Vignoli et al., 2019). Likewise to elaborate a disease model, NMR can evaluate the protein pattern of the disease in order to establish a metabolic network that configures pathophysiological processes that occur in the patient (Farber and Mittermaier, 2015). Equally, NMR has the ability to obtain microbial profiles for the broad identification of pathogens in clinical samples, in order to establish the reduction of the microbial load in the resolution of the disease (Magana et al., 2018; Kidd et al., 2020). On the other hand NMR can obtain pharmacokinetic profiles in plasma samples in order to determine the concentrations of antimicrobial drugs and if they are above the minimum inhibitory concentration (MIC) of drug that inhibits the infectious agent (Su et al., 2018). This method can also be coupled to High-Throughput Screening (HTS) platforms to evaluate metabolites in a greater number of samples and perform a robust screening of bioactive molecules against infectious diseases (Wu et al., 2015; Emwas et al., 2020). Finally, chemical methods in their robustness and their reproducibility provide information on clinical samples that must be analyzed under models of cheminformatics and bioinformatics to allow elucidate metabolites, biomarkers, as well as medications that can diagnose and treat infectious disease with a high impact (Griffiths et al., 2010; Ash et al., 2019; Balcerczyk et al., 2020).

Metabolomics and in silico tools

As important as obtaining the clinical sample and describing a metabolomic profile based on low chemical methods using targeted or untargeted strategies is a priority to have the software tools to perform an in silico analysis with which to establish a disease and an infectome (Sugimoto et al., 2012; Misra and Olivier, 2020; Majumder et al., 2021). In this way, there are several platforms used for metabolomic studies such as: BioSpider, COLMAR, FiD, HORA, MeltDB, MetaboloAnalyst, MetaboMiner, MolFind, MVAPACK, OpenMS, SetupX and XCMS(2) (Giraudeau, 2020). It is important to emphasize that most of the available metabolomic software are to analyze mass spectroscopy data, especially the open format with the end to perform a metabolome analysis through a workflow (Fig. 7) (Spicer et al., 2017; Chang et al., 2021). Thus, the metabolomic analysis is multivariate where a large number of metabolites are correlated in different stages of pathological process, so that the clinical aspects of the disease should be included, as well as the establishment of a successful and failed therapy (Gowda et al., 2008; Wang et al., 2010; Deidda et al., 2015). In this order of ideas there are web based NMR spectral databases for multivariate correlation of metabolites between them Human Metabolome Database (HMDB), Biological Magnetic Resonance Data Bank (BMRB), the Madison-Qingdao Metabolomics Consortium Database (MMCD) and the NMRShiftDB2 database (Ellinger et al., 2013; Emwas et al., 2019). In this way human metabolome database (HMDB) (<https://hmdb.ca/>) is an initiative that integrates metabolites, biological activity, metabolic pathways and diseases with spectrometry data; which allows the identification of different types of molecules that represent physiopathological processes (Shahfiza et al., 2017; Wishart et al., 2018). For this reason, metabolomics is considered to be an analysis strategy of complex biological systems that integrates information platforms to evaluate real time the different adaptations of living beings against the challenges of the environment (Pinu et al., 2019a, 2019b; Graw et al., 2021). Likewise, the metabolomic

Fig. 7 Metabolomics workflow analysis.

data obtained from the biological systems can be introduced into Machine Learning Algorithms systems that will determine the future models of precision medicine in which the predisposing causes of the disease can be evaluated and treat the patient based on his pharmacogenomics and pharmacometabolomics (Schork, 2019; Ahmed et al., 2020; Subramanian et al., 2020).

Conclusions and perspectives

The description of a human and microbial metabolic network in response to infectious diseases is the objective of metabolomic applications in the clinical practice of infectology (Robinson et al., 2019). In this order of ideas, metabolic networks are the functional expression of genomics and proteomics represented by the production of metabolites, which configures a useful and robust tool for precision medicine models (Comte et al., 2020). In this way infectious diseases require an early diagnosis, timely treatment and close monitoring to assist the process of resolving the condition, so the metabolomics is configured as a promising tool that will help the treatment of patients based on their metabolome (Mamas et al., 2011). Thus, the inclusion of strategies for metabolomic study, as well as the methods used should be included in clinical practice to develop pharmacometabolomic models that determine the progression and decision-making of infectious disease with assistance from artificial intelligence systems, with which develop algorithms with which to explore the most accurate medical possibilities in the approach of the infection (Kell and Goodacre, 2014).

Summary

Molecular pathology is an integral and essential component of diagnostic pathology, especially in the diagnosis of infectious diseases. Molecular pathology has come a long way from basic histopathological examination of tissues to aid diagnosis. The primary drivers for the emergence of this discipline are the enormous advances in molecular biology and the availability of reagents such as monoclonal antibodies. The application of molecular biology to histology, paved the way for the development of techniques such as in situ hybridization, immunohistochemistry, immunofluorescence, multiplex-staining and PCR. These techniques allow the accurate detection and localization of infectious agents in tissue samples. In this article, we describe these techniques and modifications thereof in the diagnosis of viral infections. We also discuss the advantages, disadvantages, and applicability of these methods in the context of the different types of histological tissues.

Introduction

Recent statistical estimates suggest that, there are as much as 320,000 viruses that potentially exist and could infect mammals (Anthony et al., 2013). However, to date, less than 0.07% of these have been shown to infect humans (Woolhouse et al., 2012), but the numbers are gradually increasing with new viruses being regularly discovered (Ksiazek et al., 2003; Phelan et al., 2020; Ryu, 2017; Zumla et al., 2015). Outbreak of new viruses can have enormous impact, not only on health, but also on social and economic sectors of a society. The COVID-19 pandemic illustrates this point very well (Quan et al., 2021). Thus, having rapid, specific and sensitive methods for the detection of emerging or re-emerging viruses is of paramount importance, not only during outbreaks, but also for routine diagnosis and research purposes. Traditionally, methods such as viral culture, electron microscopy, and serology were commonly used for viral detection (Payne, 2017; Storch, 2000). These techniques, albeit still used, can be very expensive, labor intensive, require several days to complete, and in many cases, have poor sensitivity, specificity or both. Advances in molecular biology, genetics and biotechnology has revolutionized the detection and diagnosis of infectious agents. New methods such as PCR-based techniques, or more recently, CRISPR-based techniques have emerged (Artika et al., 2020; Chertow, 2018). These techniques are not only highly sensitive, but they are also very rapid, and easily adaptable for routine use in diagnostic, as well as research laboratory. Additionally, some of these techniques can be used for the detection of multiple viruses from the same clinical sample simultaneously. Typical example of this is the detection of common respiratory viral pathogens, such as influenza virus, respiratory syncytial virus, adenovirus, parainfluenza virus, coronavirus, and human metapneumovirus from a single nasopharyngeal swab (Carr et al., 2010; Han et al., 2020; Mahony, 2008).

Advances in molecular biology and biotechnology has also lead to the emergence of the field of molecular pathology. Pathologists now have a much broader choice of techniques to help accurately identify or diagnose infectious diseases (Chien et al., 2001). They are no longer restricted to examining stained tissues sections under the microscope for the identification of histological or cytopathic changes in infected cells. The application of molecular tools to biopsy tissues has led to the development of techniques such as in situ hybridization (ISH), immunohistochemistry (IHC), immunofluorescence (IF) and multiplex-staining (Blom et al., 2017; Tan et al., 2020). Moreover, nucleic acids or proteins extracted from biopsies are now routinely used, not only for viral screening, but also for measuring viral load, determining viral and cellular gene expression, identifying viral sequences and

genotyping (Liloglou et al., 1994; Pan et al., 2020). These approaches are not only extremely sensitive, but they can also provide great insight into the host-viral interactions and mechanism of pathogenesis of viral-associated diseases. Single viral infected cells can now be readily identified and their cellular phenotype determined from amongst thousands of cells in a single tissue section (Huang et al., 2012; Solomon et al., 2017). With the aid of emerging digital technologies and imaging, data can also be quantitated to provide a more accurate and detailed analysis of disease processes. In this section, we discuss the different types of tissues typically available in the histopathology laboratory and some of the commonly used techniques and their applications in molecular pathology. We also discuss the main advantages, disadvantages and impact of these technique on viral studies.

Types of histological specimens

The primary type of clinical material sent to histopathology departments are tissues samples. Arguably, one of the key factor in influencing which technique or approach to use for viral studies, depends on the nature or form in which the tissue samples are available; fresh frozen, or formalin-fixed, paraffin-embedded (FFPE) or archival. Thus, it is paramount to briefly discuss these tissues before outlining the techniques used for viral detection and analysis.

Frozen samples

Frozen cryostat sections are particularly useful when rapid detection/diagnosis is required. Additionally, frozen sections are the choice of tissue to use when detecting antigens that are sensitive to aldehyde fixation and processing. Compared to FFPE tissues sections, frozen sections have much better antigen preservation, and antigen retrieval steps are not normally required for downstream IHC. Additionally, frozen sections also retain good preservation of RNA, DNA and native protein structure, which is dramatically compromised with chemical fixation (Dey, 2018). Thus, frozen tissues are suitable for molecular and genetic studies, especially if the samples are snap frozen in liquid nitrogen immediately after removal from the patient. If the sample is not going to be used on the same day, then it should be stored in -80°C to avoid degradation of nucleic acids and proteins. For cutting cryostat sections, the frozen tissue is placed on a cryostat chuck for embedding in a suitable medium like OCT (Peters, 2010). Tissue sections with $4\text{ }\mu\text{m}$ thickness are cut using a cryostat, mounted on microscopic glass slide, and kept at room temperature. The major drawback of frozen tissue is that the tissue morphology is markedly poor compared to FFPE sections. Additionally, long-term storage of frozen tissues is a major practical challenge, especially in low resource countries.

Formalin-fixed paraffin embedded samples

Formalin is a solution of formaldehyde. It is the most common chemical fixative used in histopathology. It provides excellent preservation of tissues morphology, which is arguably one of the main reasons for its routine use. Formalin-fixed tissues are processed and embedded in paraffin wax blocks. These blocks can be easily and safely stored at room temperature for decades without any major impact on tissue morphology and architecture. Paraffin-wax also provides solid support when cutting thin $4\text{ }\mu\text{m}$ tissue sections using a microtome. These sections are floated in a water bath and then picked up onto a microscopic slide. The sections are then dried by incubating in a heated chamber at 60°C . This increases their adherence capacity to the microscopic slide and clears any wrinkles left during sectioning. Prior to staining, a number of essential tissue treatment and processing steps are required (Canene-Adams, 2013).

Fixing tissues in formalin and processing them to paraffin-wax blocks is a time consuming and laborious process, prone to variations. To keep the variations to a minimum, it is important to keep some of the essential steps as standardized as possible. For example, tissues should be placed in formalin solutions as soon as possible after collection to avoid tissue degradation. Tissues should be fixed in formalin for a standard length of time. Over or under fixation can impact the subsequent results. Formalin is a protein-cross linker and although it provides good preservation of cellular and viral proteins, it does inevitably lead to their denaturation and loss of their biological activity. In some cases, denatured proteins can mask the antibody binding epitopes and hence impact IHC (Paavilainen et al., 2010). Nucleic acids are also poorly preserved in FFPE samples. Generally, DNA/RNA extracted from FFPE is typically fragmented and of poor quality (Coates et al., 1991) and not ideal for some of the molecular, genetic and sequencing studies (Mathieson and Thomas, 2020). These factors need to be taken into account when considering the use of FFPE tissues for downstream analysis of viral infections.

Archival samples

Many pathology laboratories and anatomy museums, archive tissues samples in formalin or in the form of FFPE tissue blocks. These samples are an exceptional source for biomedical research (Hassani et al., 2018; Hassani and Khan, 2015). In the past three decades, a number of truly innovative approaches and technical advances have been made exploiting archival tissues to better understand the molecular and cellular pathways underlying diseases such as cancer and infections. High throughput proteomics and genomics using tissue microarrays on FFPE archival samples has been developed (Groses et al., 2008; Kallioniemi et al., 2001; Zhang et al., 2017). Although these techniques are not yet in common routine diagnostic use, from the research perspective, they are already providing great insights into disease mechanisms and potential translational applications.

Commonly used methods in molecular pathology

Immunohistochemistry (IHC)

To visualize individual cells in the context of tissue morphology, thin tissue sections need to be appropriately stained and examined under a light microscope. Broadly speaking, there are two main approaches to staining sections for microscopy; traditional methods, and antibody-based methods. The former involve dyes that selectively bind to certain cellular structures. The most commonly used dyes are hematoxylin and eosin (H&E). Hematoxylin stains cell nuclei blue, and eosin stains cytoplasm and connective tissues pink. Although H&E staining has been used for almost 150 years and is considered the gold standard, it rarely provides any direct evidence of viral presence, except when a unique cytopathic effect (CPE) is observed with certain viral infections. Presence of Negri bodies in cells infected with rabies virus (Srinivasan et al., 2005) and owl-eye inclusions with cytomegalovirus infection (Mattes et al., 2000) are two well-known examples. More often than not, it is the antibody-based methods that allow direct identification of viral presence at the cellular level. In this approach, a specific target antigen in a cell or tissue is recognized using specific antibodies (Cotter and Loda, 2017). This technique is also known as immunocytochemistry (ICC), when performed on cells, or immunohistochemistry (IHC), when performed on tissues. While IHC has proved its effectiveness in surgical pathology to obtain diagnostic information, it can also be used to confirm viral infection, particularly when no CPE is observed (dos Santos et al., 2013). This is performed by using specific labelled antibodies against the respective viral antigen. With easy access to a range of commercially available monoclonal antibodies against specific viral components, detection of viruses by ICC/IHC has become a standard procedure in diagnostic pathology (Fig. 1). Advances in producing and labelling antibodies with markers such as enzymes or fluorescent dyes, has further expanded the use of IHC for viral studies. It is now possible to make a laboratory diagnosis of viruses such as influenza or respiratory syncytial virus from a nasopharyngeal swab in less than 30 min. Such rapid diagnostic tests have aided significantly in the management and treatment of these infections (Basile et al., 2018).

Like any diagnostic procedure, sample preparation is vital for reproducible, accurate and reliable results. For IHC, it is important to maintain the antigenicity, morphology and tissue architecture. This can be achieved through good tissue collection, appropriate fixation (formalin, quick-freezing), tissue processing and sectioning. FFPE sections between 3 μ m and 5 μ m are most commonly

Fig. 1 Common techniques used in molecular pathology. (A) Detection of EBV encoded latent membrane protein (LMP1) by IHC in a spleen section from a rabbit infected with EBV. (B) Detection of EBV by EBER-ISH in lymph node section from a patient with Hodgkin's lymphoma. The virus is present in the large malignant cells, but not the small lymphocytes (C) Detection of two different EBV proteins by double-IHC in spleen section from a rabbit infected with EBV. Brown membrane staining indicates EBV-LMP1 expression (latent marker), whilst turquoise nuclear staining indicates expression of EBV-BZLF1 (lytic marker). The staining shows the presence of both, lytic and latently infected cells in the same tissue section. (D) Combining fluorescence EBER-ISH (blue) with LMP-IHC (green) in EBV infected rabbit spleen.

used. The IHC procedure involves multiple steps; after sectioning, the tissue sections are mounted on microscopic glass slides, paraffin-wax is removed using xylene, and sections are gradually dehydrated using graded ethanol. Depending on the target viral antigen being detected and type of tissue being used, additional steps to block or quench endogenous enzyme activity or auto-fluorescence may be required (Canene-Adams, 2013). In FFPE samples, formaldehyde chemically crosslinks the proteins and in some cases this can mask target proteins from antibodies. In such cases, target antigens have to be retrieved using methods such as enzymatic, proteolytic or heat retrieval, prior to incubation with primary antibody targeting the antigen of interest.

There are a wide variety of antibodies commercially available for use in IHC. For optimal staining, it is important to select antibodies that possess low cross-reactivity and high specificity. It is critical to be familiar with the species in which the antibody is raised to prevent any cross reactivities and false positives. Antibodies can be either monoclonal or polyclonal. Each type has its own set of advantages and disadvantages. Monoclonal antibodies tend to detect a single epitope with high affinity and high specificity. By contrast, polyclonal antibodies recognizes multiple epitopes. However, unlike monoclonal antibodies, polyclonals are much more stable to changes in buffer composition, protein conformation and pH. It is important to choose a primary antibody that is highly validated, since it can affect the entire outcome of the experiment (Ivell et al., 2014).

Although monoclonal antibodies are fairly specific in binding to their respective epitope, they can nevertheless interact weakly and non-specifically with other antigens, resulting in background signals. These non-specific interactions and background signals can however be reduced or eliminated by incubating the tissue samples in blocking buffers containing bovine serum albumin (BSA), or gelatin or non-fat dry milk. Other technical aspects such as diluting or changing the antibody concentration, incubation time and temperature, can also help in reducing the background staining. Commercial blocking solutions having superior effectiveness are now also available. To check for quality control, suitable positive and negative controls must be included in each run of IHC.

For indirect IHC, secondary antibodies that recognize and bind to the primary antibody are used. Secondary antibodies are usually conjugated to reporter molecules such as enzymes (e.g., peroxidase, or alkaline phosphatase), or fluorochromes (e.g., FITC or rhodamine). Enzymatic reporter molecules reacts with their substrate to produce a colored product, which can be visualized using light microscopy. The most commonly used enzyme substrates are DAB or NBT/BCIP, which produce brown or purple colored product respectively (Fig. 1A). The intensity of the colored product can be adjusted by incubating the sections in the substrate for longer. With DAB, the signal strength can be further enhanced by including small amounts of ions such as nickel or cobalt into the substrate buffer. Fluorescent reporters are now increasingly being used in IHC. Fluorescence IHC is particularly useful for multiplex staining where several target antigens are being detected simultaneously in the same section (Fig. 1D) (Blom et al., 2017; Tan et al., 2020). Thus, it is now possible to identify viral infected cells, the cellular phenotype of the infected cells, and the phenotype of the surroundings non-infected cells in a given section. A common hurdle in the fluorescence IHC is autofluorescence, due to cellular components such as flavins, collagen, RBCs, elastin, lipofuscin and porphyrins (Croce et al., 2018; Croce and Bottiroli, 2014). Treating sections with reagents such as Sudan black and sodium borohydride, can quench the endogenous autofluorescence to some extent. Another factor to take into consideration is the long term storage of stained sections. In contrast to enzymatic IHC, sections stained using fluorescent reporters, the label can gradually fade over time with exposure to light. Once again, commercially available anti-fading agents can be used to limit this photo-bleaching effects (Renshaw, 2017).

There are various advantages of using IHC to detect viruses. It provides a histomorphologic correlation between the viral agent and host tissue responses, based on the localization of the virus and its surrounding cells. This is important in understanding the pathogenesis of viral infections. Moreover, recent advances in spatial transcriptomics is beginning to link cell types to tissues morphology, physiology and function at molecular levels, not previously possible (Crosetto et al., 2015; Lein et al., 2017; Marx, 2021). Since formalin fixation deactivated viruses, working on fixed tissues is safe and can be carried out in a standard laboratory. This is a distinct advantage, particularly when studying highly pathogenic viruses such as avian H5N1 influenza, rabies, Ebola and Crimean Congo, which normally require biosafety level 3 or 4 laboratories for handling. Additionally, IHC is suitable for detecting and studying viruses in archival material, allowing retrospective studies to be performed.

In situ hybridization (ISH)

In situ hybridization (ISH) is a technique that allows the detection and localization of viral nucleic acid (DNA or RNA) in tissue sections or cytological specimens using labelled nucleic acid probes with complementary sequences to the target viral nucleic acid. Over the past three decade, ISH has been increasingly used in research laboratories for studying viral-associated diseases. However, its use in diagnostic laboratories has been limited. Relative to other methods such as IHC and PCR, ISH is much more specialized, time consuming and not easily amendable for automation.

ISH can be performed on most kinds of cell and tissue preparations, including smears, cytopspins, FFPE and snap frozen sections. Since ISH involves targeting viral DNA or RNA, it is important to fix or snap freeze the tissues as soon as possible. This is particularly essential if viral RNA is being targeted for detection; RNA has a fairly short half-life and starts to degrade within minutes after collection. The complementary probes used to detect target nucleic acids, can be RNA probes (riboprobes), single stranded DNA (ssDNA) probes, double stranded DNA (dsDNA) probes, or synthetic oligonucleotides (oligoprobes) (Braz et al., 2020; Urbanek et al., 2015; Wu and Wang, 2019). To make the target nucleic acid accessible to the probes, the sections are usually pretreated by proteolytic digestion. Probe and tissue DNA also need to be denatured, either by thermal, alkaline or acid treatment to form a single strand and allow hybridization to occur. The most convenient method is heating the tissue sections with the probe for a few minutes at 90–100 °C. The probe is then allowed to hybridize to its target DNA/RNA, most often by incubating overnight in a heated oven at

around 37–45 °C. Following post-hybridization washes to remove the non-hybridized labelled probed, the sections are incubated in primary antibody against the target label. The sections are then washed to remove the unbound primary antibody and the sections are incubated in secondary antibody, conjugated to an enzyme or fluorescent reporter. These steps are the same as those for IHC described above. In the early days when ISH was first introduced, radioisotopes such as P^{32} were frequently used to label the complementary probes (Chen et al., 2012; Niedobitek and Herbst, 2003). However, this approach was much more cumbersome and required designated facilities and handling precautions. Moreover, it was time consuming, it had poor resolution and it was limited by the short-life half of the labelled probe. The use of non-radioactive haptens such as digoxigenin or biotin changed all of this. The method became much more user friendly, rapid, had higher resolution and the stained slides could be stored easily and safely for archiving.

Non-radiolabeled ISH is now well-established in molecular pathology laboratories for research on viruses. The technique can be used, not only to detect a virus in the context of tissue morphology, but also the cellular phenotype of the infected cells and extent of infection. Additionally, ISH has played an important role in helping to discriminate between an etiological and non-etiological role of viruses in disease pathogenesis, especially for viruses that are highly prevalent in the human population. For example, Epstein-Barr virus (EBV) is an oncogenic virus asymptotically carried by over 90% of the people worldwide. Using ISH, it was demonstrated that this common virus was present in the malignant cells of approximately one third of all cases of Hodgkin's lymphoma and hence, etiological associated with the disease (Fig. 1B), but other common herpesviruses such as cytomegalovirus (CMV) or human herpesvirus-6 (HHV-6) were absent (Khan et al., 1993). In other malignancies such as breast cancer, it was shown that EBV was present in occasional infiltrating lymphocytes and not malignant cells, thus unlikely to be involved the disease process (Khan et al., 2011). Similarly, using ISH, high-risk HPV subtypes can be detected in cervical cancer (Sheng et al., 2013). ISH has also been used to detect viral DNA or RNA in human tissues (McDougall et al., 1986). Combination of ISH and IHC can provide the simultaneous detection of viral nucleic acids as well of viral or cellular proteins (Fig. 1D).

Polymerase chain reaction

Polymerase chain reaction (PCR) first described in 1985, is a simple technique to detect and amplify gene segments from DNA or RNA (Saiki et al., 1985). PCR is by far the most sensitive technique employed in various clinical and microbiological laboratories to detect etiological agents in cells, tissues and body fluids. In the last 20 years, it has proved to be a useful tool for gene analysis in a quick and streamlined fashion. This Nobel Prize winning technique revolutionized the detection and analysis of nucleic acids (Shampo and Kyle, 2002). Using PCR, it became possible for the first time to amplify and analyze DNA from archeological samples of extinct species such as the woolly mammoth and the dinosaurs (Hoss et al., 1994; Poinar et al., 2006; Woodward et al., 1994). This technical advance gave a glimpse into evolutionary past of these species. Similarly, PCR-based approach allowed the discovery of new viruses from specimens dating back tens of thousands of years (Legendre et al., 2014; Philippe et al., 2013).

PCR generates abundant DNA in a simple reaction tube by selectively and specifically amplifying the target sequence from amongst cellular genome, which is usually 1000s of fold in excess. It is like being able to detect a needle in a haystack. The technique is not only very sensitive and rapid, but it is also fairly versatile. It can be used to amplify and analyze specific DNA or RNA sequences from a wide variety of specimens, including peripheral blood, urine, CSF, swabs, and histological samples such as FFPE and needle-biopsies (Valones et al., 2009). The molecular data acquired by PCR, combined with the observational expertise of the histopathologist, can help shed light on disease onset, progression and its response to therapy.

A number of new modifications and adaptations have been made to the basic PCR methodology, including in situ PCR, quantitative PCR (qPCR), reverse transcriptase PCR (RT-PCR), nested PCR and multiplex PCR. The basic principle however, remains unchanged (Diss, 2003). Target sequences are amplified using synthetic oligonucleotides having complementary sequences to the regions flanking the target sequence. These oligonucleotides act as primers for heat stable enzyme Taq polymerase. Repeated cycles of heat denaturation of the test DNA, annealing of primers to their target sequences, and extension of the annealed primers by the Taq polymerase, results in the exponential amplifications of the target sequence. The amplified product can be analyzed or sequenced. Using multiple primers against several different infectious agents, PCR permits the screening of multiple potential etiological agents in a single sample (Wittwer et al., 2001). This is particularly useful for conditions such as respiratory tract infections, which are often indistinguishable on clinical presentation but can be caused by a variety of different viruses and bacteria (Mengelle et al., 2014; Zumla et al., 2014). Further adaptation of multiplex PCR with qPCR allows simultaneously real-time quantification of several targets (Hawkins and Guest, 2017).

In many research laboratories, nucleic acid analysis has become largely automated for identification for multiple viruses. This key feature has pushed qPCR from research laboratories to diagnostics. Relative quantification generally delivers sufficient data and is easier to analyze. However, absolute quantification is necessary when an infection is being monitored. This helps in interpreting the data in a global context, allowing universal approach to downstream interventions. For example, viral load can be used as an indicator to determine whether the selected treatment regimen is working or not. By quantifying the viral load, virus-host interactions, extent of infection and compliance to anti-viral therapy, as in the case of HIV, can be determined (Bhatti et al., 2016; Saag et al., 2020). The severity of the disease progression can also be determined by qPCR by studying viral presence, reactivation and persistence. qPCR is commonly used for detecting and monitoring EBV viral load in organ recipients who may be at increased risk of developing post-transplant lymphoproliferative disorders (Dierickx and Habermann, 2018). Similarly, quantitative measurements of other viruses, such as cytomegalovirus (CMV), varicella zoster virus (VZV) and BK polyomavirus in transplant recipients, can help in the early identification of patients at risk of complications (Kotton and Fishman, 2005; Vanichanan et al.,

2018). To determine disease progression, quantification of viral loads at several time points is critical. Moreover, PCR is a common tool used for the identification and characterization of emerging pathogens (Zhou et al., 2020). Although PCR is rapid and extremely sensitive, it is prone to contamination and precautions have to be exercised. Tissue samples fixed in formalin are often not suitable for amplifying large sequences, since the fixative causes DNA damage (Srinivasan et al., 2002). Moreover, some of the tissue collection and processing steps, such as autopsies, are not usually performed in sterile conditions and this can increase the risk of contamination.

Multiplex-staining

Although conventional IHC is well established and indispensable in diagnostic pathology, it does have its limitations. Using light microscopy, the technique only allows for one marker to be detected per tissue section. This limitation has led to the development of double-staining procedures, targeting two separate antigens (cellular or viral) using two different chromogenic reporters (Fig. 1C). An important consideration in this procedure is the appropriate selection of the primary antibodies. For indirect IHC, the two primary antibodies have to be from different species (e.g., mouse and rabbit) or at least be of different isotype to avoid cross-reactivity and false positives. Primary antibodies from different species can be mixed and applied to the section at the same time. Additionally, the secondary antibodies (e.g., anti-mouse and anti-rabbit) have to be conjugated to different enzymes requiring different chromogenic substrates. The resultant enzymatic reaction should lead to two distinct colors easily distinguishable under the light microscope. Commonly used combinations include, DAB with peroxidase, and fast red or new fuchsin or nitro blue tetrazolium (NBT) with alkaline phosphatase (Lojda et al., 1979).

Double staining, combining IHC with ISH is also now well established (Fig. 1D). Although both of these techniques target different types of molecules (IHC targets proteins whilst ISH targets nucleic acid), they provide results that are complementary. Using a combination of IHC and ISH, it has been possible to identify not only the phenotype of the infected cells, but also what viral genes are expressed at RNA level. Such combination of double-staining have been used for studying a number of different viruses, including EBV, HIV and more recently SARS-CoV-2 (Lean et al., 2020; Nakajima et al., 2003; Takahashi et al., 2020). One major drawback to determining viral gene expression is the fact that mRNA is unstable and degrades fairly quickly. Thus, long-term archival FFPE tissues are often unsuitable for this procedure.

Although, the double-staining methods are a notable advance, compared to the single staining methods, they nevertheless still fail to provide a comprehensive and global analysis of infected tissues. The fact that tissue sections typically consist of multiple types of cells, the proportion and arrangement of which can change in disease states, the ability to stain and visualize multiple components in a tissue is clearly important. Advances in antibody design, production and labelling chemistries, coupled with better imaging technologies, have facilitated the development of multiplex-IHC (McGinnis et al., 2021). It is now possible to stain multiple cellular and viral markers simultaneously, providing a more comprehensive analysis of tissue composition, cellular functions, and cell to cell interactions in a single tissue section (Ilić et al., 2018; Tan et al., 2020). More recently, the principle of multiplex-IHC has been extended to multiplex-ISH, allowing 1000s of targets, viral and cellular, to be detected at cellular level (Femino et al., 1998; Lee et al., 2014). This spatial transcriptomics approach is providing an unprecedented and truly global picture of the location, distribution and the interaction of the infected cells with the surrounding cellular milieu (Lein et al., 2017; McGinnis et al., 2021). Moreover, these multiplex staining platforms are being developed to be applicable to FFPE tissues, and making the technique suitable for both routinely processed tissues as well as archival (Decalf et al., 2019). Additionally, the fact the FFPE tissues retain excellent tissue architectural morphology, provides excellent resolution at single cell level.

Concluding remarks

The last 50 years have seen unprecedented advances in molecular biology, genetics and biotechnology. These advances, coupled with equally remarkable progress in imaging and digital technologies, is revolutionizing research and laboratory diagnosis of infectious diseases. However, some of these novel and advanced techniques, require sophisticated equipment, technical expertise, and are expensive to run. Moreover, in many cases, the comprehensive information gained from these methods, albeit very useful for research purposes, does not always help in clinical decision making and patient management. With a focus on precision medicine, current research efforts are aimed at making these novel diagnostic technologies rapid, sensitive, accurate, low-cost and preferably applicable to point-of-care testing (Drain et al., 2014) (Table 1).

Table 1 Techniques commonly used in molecular pathology for the detection of viruses in histopathological samples.

<i>Technique</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>Comments</i>	<i>References</i>
Polymerase chain reaction (PCR)	• Less labor intensive. • Highly specific and quantitative. • Large dynamic range. • Can detect multiple viral genotypes in single reaction. • Quick detection of viruses. • Higher sensitivity than ISH and IHC. • Can determine the viral load. • Widely used in clinical diagnostics.	• Affected by inhibitory compounds and artifacts. • Risk of contamination. • Special equipment and qualified personnel required. • No histomorphologic correlation. • Reduced sensitivity for formalin fixed samples. • Knowledge and expertise required to design primers and probes.	• Nucleic acids extracted from FFPE samples may not always be suitable for molecular analysis. • Archival samples may also affect the nucleic acid specificity and sensitivity.	Dedhia et al. (2007), Diss (2003), Mackay et al. (2002), Pan et al. (2020), Reta et al. (2020), and Watzinger et al. (2004)
In situ hybridization (ISH)	• Highly specific than IHC. • Offers histomorphologic correlation. • In-house probes could be synthesized with known sequence. • Offers histomorphologic correlation at nucleic acid level. • High reproducibility.	• Lower sensitivity than IHC. • Increased time and cost. • Prolonged fixation in formalin may affect the sensitivity. • Difficult to detect the targets with low DNA or RNA copies. • Not widely used in clinical diagnostics.	• Higher sensitivity of RNA transcripts in frozen sections due to enhanced preservation of RNA.	Kelesidis et al. (2011), Mesa and Lilia (2013), Niedobitek and Herbst (2003), Roe et al. (2019), and Sheng et al. (2013)
Immunohistochemistry (IHC)	• Higher sensitivity than ISH • Offers histomorphologic correlation. • Testing several samples simultaneously. • Can reduce the potential risk of exposure. • Used in Clinical diagnostic analysis.	• Availability of antibodies. • Cross-reactivity antigens in tissues. • Semi-quantitative. • Variability depends upon type of fixation. • Interpretation of results is subjective.	• Archival samples stored for decades can be analyzed. • Viral infections whose initial causes are unknown can be characterized.	Bramhachari et al. (2019), Chien et al. (2001), Grillo et al. (2017), and Reta et al. (2020)
Multiplex-staining	• Can detect multiple viral genes (Double staining), DNA or RNA (Dual ISH-IHC). • Histomorphologic correlation between viral and cellular markers can be achieved. • Reduced turn-around time.	• Reduced mRNA signal through peroxidase reaction. • Labor intensive and Cross-reactive. • Not used in clinical diagnostics. • Extensive knowledge is required. • Possibility of tissue damage and antigen loss.	• Potential to evaluate topographical correlation and cellular tropism of the virus.	Fayyadh et al. (2017), Ko et al. (2019), Lopez (2014) and Sood et al. (2020)

Introduction

Bacteria and fungi that attach to surfaces of medical devices, including endotracheal tubes, central vascular catheters, cardiac pacemakers, tissue fillers, breast implants, urinary catheters, and orthopedic implants, may build biofilms (Khatoon et al., 2018). They also are responsible for up to 80% of bacterial infections in humans, such as chronic otitis media, periodontitis, endocarditis, biliary tract infection, urinary tract infection, osteomyelitis, and chronic wounds (Khatoon et al., 2018). Owing to the difficulty of killing biofilms, contaminated indwelling devices must be removed, which results in high cost and complications for the patient (Costerton et al., 1999). Biofilm development can be grouped into four stages (O'Toole et al., 2000). Planktonic bacteria initially attach to the surface and then develop into a sessile growth stage (O'Toole et al., 2000). As biofilms mature, some cells disperse into the surrounding environment as planktonic cells and become the basis for biofilm formation on new surfaces.

Bacteria in biofilms are resistant not only to the immune system but also to treatment with antibiotics (Davies, 2003). By preventing bacteria from being recognized by immune cells and activating response regulators that can influence the activities of immune cells, biofilms can resist the host immune defense systems (Leid, 2009). Nickel et al. reported that sessile cells of *Pseudomonas aeruginosa* were approximately 1000 times more resistant to tobramycin than planktonic cells (Nickel et al., 1985). The reasons why biofilms have high antibiotic resistance include retarded penetration of antimicrobial agents, extracellular polymeric substances (EPS), decreased metabolic activity of cells within biofilms, protective properties of dormant persistent cells, presence of small colony variants, and efflux pump activity (Davies, 2003).

When compared to diverse biofilm flow models, such as CDC Biofilm Reactors, Drip Flow Biofilm Reactors, and Robbins devices, static biofilm models are able to quantify biofilm formation by many bacterial strains in various growth settings (Azeredo et al., 2017; Coenye and Nelis, 2010; Catto and Cappitelli, 2019). They are fast, cost-effective, uncomplicated, do not require special instruments, and they can simultaneously test many samples (Magana et al., 2018). Static models can be employed to: identify genes associated with biofilm formation (Conlon et al., 2002, 2004; Valle et al., 2003); investigate environmental factors (such as growth media, glucose, sodium chloride, ethanol, pH, temperature, and time) influencing biofilm formation (Pan et al., 2010; Dimakopoulou-Papazoglou et al., 2016; Tango et al., 2018); test the effects of modified surface materials (such as anti-adhesive polymers, nitric oxide-releasing compounds, reactive oxygen species-releasing compounds, photoactivable compounds, and

antibacterial nanostructured materials) on biofilm formation (Tabbasum et al., 2021; Raad et al., 2008; Puckett et al., 2010); as well as to evaluate agents that inhibit biofilm formation (Cady et al., 2012; Chen et al., 2018; Kim et al., 2018; Cao et al., 2019; Przekwas et al., 2020). However, they can produce varied results of biofilm formation depending on laboratories, inoculum concentrations, washing conditions, and other factors (Bahamondez-Canas et al., 2019). Since fresh nutrients are not provided continuously in static biofilm models, it is not easy for them to form mature biofilms (Bahamondez-Canas et al., 2019). Also, there is a disadvantage in that they are not able to represent in vivo states in which bacterial cells undergo shear stress in continuous flow conditions (Bahamondez-Canas et al., 2019; Waters et al., 2014). Nevertheless, static biofilm models are very important models to study biofilm formation. They make it possible to enumerate viable cells, measure stained biofilms microscopically and macroscopically, and differentiate live and dead sessile cells (Djordjevic et al., 2002; Olszewska et al., 2020). The three static biofilm models include the colony biofilm model (CBM), air-liquid interface model (ALIM), and microtiter plate model (MPM) (Conlon et al., 2002; Rani et al., 2007; Yonezawa et al., 2009).

Biofilm detection methods can quantify biofilms and measure live or dead cells within biofilms (Azeredo et al., 2017). Among the various biofilm detection methods, researchers can choose one of the methods depending on accessible techniques, instruments, and specific research purpose. Staining methods, such as crystal violet (CV), 2,3-bis-(2-methoxy-4-nitro-5-sulphophenyl)-2H-tetrazolium-5-carboxanilide inner salt (XTT), and 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), are the most widely used and are capable of being applied to measure biofilm biomass and live or dead cells (Gabrielson et al., 2002; Paytubi et al., 2017; Traba and Liang, 2011). Microscopy methods, such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), confocal laser scanning microscopy (CLSM), and atomic force microscopy (AFM), are essential tools for characterizing biofilm structures since they are able to show spatial organization of biofilms (Stokes, 2003; Graham and Orenstein, 2007; de Carvalho and da Fonseca, 2007; Handorf et al., 2019).

In vitro static biofilm model

Colony biofilm model (CBM)

CBM, which cultures bacterial biofilms on membrane filters deposited on agar media, has been used to examine antibiotic penetration through biofilm forming cells (Fig. 1) (Singh et al., 2010). The agar media supply nutrients and thick biofilms can be produced by transferring biofilms grown on the filter to fresh media (Wahlen et al., 2018). This model has the advantage that biofilms can be grown in an air-membrane interface without culturing them in liquid media that are not easy to process. Unlike most biofilm growth models, CBM can efficiently replace the energy source or antibiotics without a washing step. Additionally, it allows multiple tests to be run simultaneously by simply increasing the number of membrane filters on the agar medium. It is spatially heterogeneous, with sessile cells of different growth stages existing according to oxygen and nutrient availability (Nadell et al., 2009). Metabolically active cells occupy an air-biofilm interface rich in oxygen, but dead or dormant cells populate the inner biofilm structure (Nadell et al., 2009). CBM is able to form a thick biofilm on agar media in a short time; the thicknesses of *P. aeruginosa* and *Staphylococcus epidermidis* biofilms after 48 h of growth were about 150–300 and 100 μm , respectively (Stewart et al., 2007; Werner et al., 2004).

The number of viable cells obtained following antibiotic treatment in CBM directly reflects cell death rather than biofilm dissociation (Singh et al., 2010; Walters et al., 2003; Anderl et al., 2000). Cells in the colony biofilms may be enumerated by the plate count method and penetration of antimicrobial agents through biofilms can be measured by the diameters of inhibition zones. Epifluorescence, electron microscopes and oxygen electrodes may be employed to assess local antimicrobial action, extracellular components, protein production activity, DNA replication, and oxygen concentration. CBM has also been employed to model wound biofilm infections and test the effects of large amounts of antimicrobial dressings since the external areas of agar media and infection sites are similar (Agostinho et al., 2011; James et al., 2016). Microorganisms with different motility structures can swim or glide over the membrane filter at varying rates, so care should be taken when preparing for CBM (Josenhans and Suerbaum, 2002). Because CBM forms dense colony biofilms, dispersion of sessile cells from the membrane filter may be done by vortexing, sonication and subsequent bacterial counting, but these procedures are time-consuming and require a great deal of work.

Air-liquid interface model (ALIM)

At the interface between air and liquid, aerobic or facultative aerobic microorganisms utilize both oxygen and nutrients at the same time. Most biofilm experiments are performed in liquid media, but multiple bacteria (including *Acinetobacter baumannii*, *Bacillus*

Fig. 1 View of colony biofilm model.

cereus, *B. subtilis*, *Escherichia coli*, *Listeria monocytogenes*, *Mycobacterium smegmatis*, *Pectobacterium carotovorum*, *P. aeruginosa*, *P. fluorescens*, *Salmonella enterica*, *Shewanella oneidensis* and *Vibrio cholerae*, as well as the fungi *Candida albicans* and *Saccharomyces cerevisiae* have been known to form biofilms at the air-liquid interface (Abriat et al., 2020; Crespo Tapia et al., 2018; Medrano-Felix et al., 2018; Haque et al., 2017; Sochorova et al., 2014; Zara et al., 2012; Koza et al., 2009; Therien et al., 2020; Oh and Han, 2020; Okshevsky et al., 2018). These organisms are aerotactic and can move towards oxygen above liquid media (Taylor et al., 1999). Bacteria colonizing the interface between air and liquid, forming a pellicle, are involved in respiratory tract infections, biodegradation of hydrocarbons, and improved oil recovery (Matsui et al., 2006; Hu et al., 2013). To make the pellicle, microorganisms can stick to the wall of the test tube, produce a molecule to modify surface tension, swim to reach the air-liquid interface by flagella, or entrap CO₂ generated during glucose fermentation (Angelini et al., 2009; Koizumi et al., 2008; Robertson et al., 2013; Okshevsky et al., 2018). ALIM can be performed in glass or polystyrene test tubes or multi-well plates in either horizontal or tilted positions (Fig. 2) (Yonezawa et al., 2009). Alternatively, glass or plastic coverslips can be placed at angles of 30–90 degrees to wells (Ramalingam and Lee, 2019). After biofilm formation, a conventional, fluorescence, CLSM, or electron microscopy (EM) can be used to visualize biofilms (Ramalingam and Lee, 2019; Wang et al., 2017; Yonezawa et al., 2009). In addition, the air-liquid interface biofilms can be determined by weighing wet or dry biofilm biomass or counting the number of bacteria with a standard plate count method (Pisithkul et al., 2019; Scher et al., 2005). ALIM has been employed in assessing biofilm susceptibility to chlorine, handwashes, sanitizers, heat, sodium chloride, low pH and low concentrations of ethanol (Scher et al., 2005; Tashiro et al., 2014; Ahmed et al., 2020). Meza-Villezas et al. and Li et al. investigated the effect of antibacterial nanocomposites and dental adhesives in the air-liquid biofilms of *V. cholerae* and dental bacteria, respectively (Meza-Villezas et al., 2019; Li et al., 2014). Biofilm formation capabilities of psychrotrophic pseudomonads, *S. enterica*, and *S. cerevisiae* isolated from spoiled meat, water or feces, and wine, can also be compared using ALIM (Medrano-Felix et al., 2018; Robertson et al., 2013; Zara et al., 2012).

Microtiter plate model (MPM)

MPM has been utilized the most in the static biofilm system and allows quantitation of in vitro biofilm formation on abiotic surfaces (Figs. 5–8) (Paytubi et al., 2017; Peeters et al., 2008a). Biofilms can be cultured on both the bottom and walls of multi-well culture plates (Chon et al., 2020; Peeters et al., 2008a). After biofilm formation, either the planktonic cells are removed and biofilms adhering to the microplate surface are washed and directly stained, or biofilms are detached and the number of bacterial cells is counted to quantify biofilm growth. Different sizes (6-, 12-, 24-, 48- or 96-well) of plates, surface treatments (tissue-culture treated or poly-D-lysine surface), surface materials (polystyrene, polypropylene or polyvinyl chloride), and well shapes (flat, conical, easy wash, round or V-bottom) can be selected according to the research purpose. Coupons, disks or catheter segments impregnated with antimicrobial agents can also be placed in the multi-well plates to investigate biofilm growth (Poilvache et al., 2020; Chandra et al., 2018; Chong et al., 2021).

MPM has the disadvantage of depleting nutrients or concentrating signaling molecules, as nutrients are not continuously supplied (Hunt et al., 2004). Although fresh nutrients can be regularly replaced throughout the experiment, biofilms may be detached while planktonic cells are discarded. Another drawback of MPM is evaporation of liquid nutrients during long-term incubation in the outer wells of multi-well plates at 37 °C, the most common temperature used in investigating biofilm formation (Das et al., 2017). The loss of bacterial culture media leads to concentration of certain ingredients and changes in osmolarity, which can have a profound effect on biofilm formation. To minimize evaporation, the microplates can be sealed with a sterile adhesive film or sterile water can be pipetted into peripheral wells. Compared to the dynamic biofilm systems, MPM is simple, easy to use, rapid, and does not require an expensive instrument to quantify biofilm formation. In addition, a large number of samples can be run at once using 96-well plates. It has been applied widely to test the ability of bacteria to form sessile cells in vitro and to investigate the effects of bile, serum, fibrinogen, milk components, and cigarette smoke condensate on biofilm production. MPM has also been used to screen biofilm formation-defective mutants, examine the interaction between mixed bacteria during biofilm formation, and assess anti-biofilm activities of: antibiotics, bacteriophages, antagonistic and probiotic bacteria, enzymes (α -amylase, dispersin B, DNase I, lactonase, and proteinase K), small molecules (aryl rhodanines, *cis*-2-decenoic acid, ebselen, and terrein), nanomaterials (silver and chitosan nanoparticles, silver-titanium composites, and nanostructured titania coating with silver nanoparticles), biocides (benzalkonium chloride and sodium hypochlorite), quorum-sensing inhibitors (eugenol, cinnamaldehyde, ellagic acid, and curcumin), and plant-derived natural compounds (ursolic acid, naringenin, and xanthorrhizol) (Vandenbosch et al., 2010; Shakeri et al., 2007; Peeters et al., 2008b; Quave et al., 2008; Brackman et al., 2009; Amorena et al., 1999; Dong et al., 2020; Kazmierczak et al., 2021; Phee et al., 2013; Jiang et al., 2020; Chung and Toh, 2014; Ramasamy and Lee,

Fig. 2 Air-liquid interface biofilms stained with crystal violet. (1) *Pseudomonas aeruginosa* ATCC 27853, (2) *P. aeruginosa* PA14, and (3) *P. aeruginosa* PA01. Biofilms were grown for 72 h at 37 °C and stained with 0.1% crystal violet.

2016; Rabin et al., 2015; Ta and Arnason, 2015; Mishra et al., 2020; Peters et al., 2012; Toyofuku et al., 2016). Numerous experimental data have made it possible to elucidate the mechanism by which bacteria form biofilms on various material surfaces.

Since some bacterial cells freely floating in MPM may settle at the bottom of the wells and be trapped in EPS, it is difficult to consider biofilms accumulated on the bottom as pure biofilms. The MBEC Assay Biofilm Inoculator, formerly known as a Calgary Biofilm Device, is a tool to overcome the shortcomings of the static MPM mentioned above and has been employed to test anti-biofilm susceptibilities of antimicrobial agents (Nowatzki et al., 2012). It contains a lid with polystyrene pegs that are submerged in broth media, provide solid surfaces for biofilm attachment and formation, and can be coated with hydroxyapatite, titanium dioxide, or other materials (Obaid et al., 2016). The pegs may be removed from the lid. Bacterial cell numbers in biofilms can be enumerated by standard plate count methods, following repeated vortexing and sonication, or biofilm cells can be examined by microscopic techniques (Rodrigues et al., 2011). Since it is not difficult to move the pegs to new well bases containing antimicrobial agents after biofilm growth, the MBEC Assay Biofilm Inoculator has the advantage of being able to test the antibiotic sensitivities of biofilms obtained from long-term incubation (Chen et al., 2020). Biofilms formed in MPM can be measured by the number of viable bacterial cells, the BioFilm Ring test, biomass staining (crystal violet or Syto 9/propidium iodide) or metabolic activity assays (resazurin, adenosine triphosphate (ATP), XTT, or MTT) (Chavant et al., 2007; Hofmann et al., 2012; Nascimento et al., 2014; Peeters et al., 2008b; Ahmad et al., 2021; Kamauchi et al., 2021; Tiwari et al., 2021).

BioFilm ring test (BRT)

BRT is a kit designed to quickly test for effective antimicrobial agents against biofilms in the early stages (Fig. 3) (Olivares et al., 2020; Cremet et al., 2013). After bacteria are mixed with inert magnetic microbeads in the bottom of a 96-well microplate, biofilms are incubated at the desired temperature and time, and then exposed to a magnetic field to capture the microbeads that are not entrapped by sessile cells (Valour et al., 2013). BRT does not require a washing or staining step, so the bias due to experimental

Fig. 3 Biofilm profiling of *Pseudomonas aeruginosa* clinical isolates according to their ability to block the migration of magnetic microbeads in clinical Biofilm Ring Test assay. Biofilm formation in 96-well polystyrene plates is shown after 5 h of incubation at 37 °C for representative strains of three adhesion profiles: strain #22 (no-biofilm producer), strain #2 (weak-biofilm producer) and strain #21 (moderate-biofilm producer). A gradual blocking of beads was noticed, depending on the microbial serial dilutions, and therefore reflects the strength of the biofilm produced by bacteria. Images were obtained after magnetization of the plates on the block test and scanning with the plate reader. Negative controls with only Brain Heart Infusion (BHI) medium and magnetic microparticles are displayed in the last line of microplates. Reprinted with permission from Olivares E, Tasse J, Badel-Berchoux S, Provot C, Prévost G and Bernardi T (2020) Clinical Biofilm Ring Test® Reveals the Potential Role of β -Lactams in the Induction of Biofilm Formation by *P. aeruginosa* in Cystic Fibrosis Patients. *Pathogens* 9(12):1065. <https://doi.org/10.3390/pathogens9121065>.

personnel is relatively small and reproducibility is high. Moreover, it has been coined the Antibiofilmogram method to test biofilm susceptibility of clinical isolates to antibiotics (Tasse et al., 2016). BRT cannot provide information on the detailed structure or thickness of biofilms (Puig et al., 2014). It has been employed to test the effect of cranberry juice, EPS produced by marine biofilm-forming bacteria, and metal-N-heterocyclic carbene complexes against biofilm formation. It has also been used to characterize the association between biofilm phenotype and clonal lineage, to examine the kinetics of biofilm formation in various Gram-positive and -negative bacteria, and to study the role of β -lactam antibiotics in induction of biofilm formation (Abriat et al., 2020; Olivares et al., 2020; Flament-Simon et al., 2019; Brian-Jaisson et al., 2016; Bernardi et al., 2014; Tre-Hardy et al., 2009).

Biofilm measurement

Agar plate counting of viable biofilm cells

Biofilms harvested from CBM, ALIM, and MPM can be plated on appropriate nutrient agar plates through serial dilution following the detachment process, and the number of live bacterial cells can be counted. Plate counting is a reliable and sensitive technique, generally referred to as the gold standard, for bacterial enumeration in biofilms; various bacteria can also be counted at the same time (Table 1). However, it is time-consuming and requires a lot of labor and experienced laboratory personnel. Even though optimal selective culture media and culture conditions are required for multi-species biofilms, plate counting has the advantage of selectively quantifying the desired bacterial species. However, false-negatives can occur if bacterial species are grown under conditions below the detection limits of selective culture media containing antibiotics (Vandecandelaere et al., 2012). The presence of some fastidious, stressed, viable but non-culturable bacteria or unculturable bacteria in biofilms can also lead to false-negative results (Xu et al., 2012). To overcome these problems, molecular techniques such as quantitative real-time polymerase chain reaction, fluorescence in situ hybridization (FISH) using peptide nucleic acid probes, and pyrosequencing can be used to detect DNA from bacteria present in multi-species biofilms (Lopes et al., 2018; Xu et al., 2012; Vandecandelaere et al., 2012).

Viability assessment by SYTO 9/propidium iodide (PI) staining

A live/dead cell staining technique using SYTO 9/propidium iodide (PI) has been used to observe biofilm structure and is commercially available as a kit (Fig. 4) (Ong et al., 2019; Hofmann et al., 2012). SYTO 9, a green fluorescent dye, can penetrate bacterial membranes and bind to nucleic acids of live and dead biofilm cells, whereas PI, a red fluorescent dye, can stain only injured or dead cells (Tawakoli et al., 2013). The stained biofilm samples can be visualized and characterized by a microplate reader, flow cytometry or CLSM (Table 1). Even if bacterial cells in biofilms are killed by antimicrobial agents, if PI does not penetrate their membranes, they are recognized as viable cells (Latka and Drulis-Kawa, 2020). Therefore, total bacterial cell numbers obtained from standard plate counting and viable cell estimation observed by the SYTO 9/PI staining method may not match. Combinations of SYTO 9 and PI dyes may cause high background signals and crosstalk between channels of staining dyes, which makes it difficult to accurately interpret viability of biofilm samples (Bahamondez-Canas et al., 2019). Further, when SYTO 9 dye is used with PI, rapid photobleaching occurs. SYTO 9 dye tends to stain dead cells better than viable cells; additionally, it is not easy to measure the total number of cells of Gram-negative bacteria in biofilms by this method (Stiefel et al., 2015). Some researchers have also employed SYBR green and acridine orange (3-N,3-N,6-N,6-N-tetramethylacridine-3,6-diamine) as a substitute for SYTO 9 (Passerini de Rossi et al., 2007; Feng et al., 2014). The SYTO 9/PI staining technique has been broadly applied to determine the effects of the following against biofilms: antibiotics (clindamycin, clotrimazole, econazole, tobramycin, and vancomycin), an antimicrobial peptide [S4 (1-16) M4Ka], blood platelets, phages (*Klebsiella* phage KP34), chitosan, nanoparticles [silver, poly(D,L-lactide-co-glycolide)], disinfectants (chlorine, monochloramine, chlorhexidine, sodium hypochlorite, and benzalkonium chloride), nitric oxide, photosensitizers (octa-cationic zinc phthalocyanines), heterocyclic compounds (thiazolidinedione and succinimide derivatives), essential oils (carvacrol, citronellol, eugenol, terpineol, *trans*-cinnamaldehyde), lactoferrin chimera, *Scutellaria baicalensis* (Chinese Skullcap), manuka honey, grape seed extract, high-fructose corn syrup, propolis, synthetic flavonoids, casein phosphopeptide-amorphous calcium phosphate, calcium hydroxide, and antimicrobial coatings (polytetrafluoroethylene, silver electrodeposition, and triethoxysilylpropyl succinic anhydride silanization) (Bahamondez-Canas et al., 2019; Pantanella et al., 2013; Hannig et al., 2010; Welch et al., 2012; Latka and Drulis-Kawa, 2020; Magana et al., 2018; Olszewska et al., 2020). Additionally, it has been applied to investigate acid tolerance of biofilms, biofilm development of an oral polymicrobial community and dental unit water lines, the role of mastoid mucosal biofilms in chronic otitis media, biofilms of bronchoalveolar lavage, biofilms in endotracheal tube, and biofilm detection in chronic rhinosinusitis patients and drinking water distribution systems (Welin-Neilands and Svensater, 2007; Chavez de Paz, 2012; Lampikoski et al., 2012; Marsh et al., 2015; Fernandez-Barat et al., 2012; Li et al., 2012; Waller et al., 2018).

Assessment of the total biomass by crystal violet (CV) staining assay

CV is used in Gram staining to differentiate between Gram-positive and -negative bacteria and is the most common staining method to measure the total biomass of sessile cells in both ALIM and MPM (Figs. 2, 5, 7 and 8 and Table 1) (Paytubi et al., 2017; Merritt et al., 2005). After bacteria are grown for the desired time at an appropriate temperature in a test tube or multi-well plate, unadhered planktonic cells are carefully discarded and washed with sterilized distilled water. Then, 0.1–1.0% CV solution is added, incubated at room temperature for 10–30 min, and rinsed with sterile distilled water (Chon et al., 2020). Stained sessile cells are dried and the

<i>Methods</i>	<i>Application</i>	<i>Advantages</i>	<i>Disadvantages</i>	<i>References</i>
Agar plate counting of viable biofilm cells	Counting of the number of live bacterial cells	Reliable, sensitive technique Count various bacteria simultaneously Selectively quantify the desired bacterial species in multi-species biofilms	Time consuming Require a lot of labor and experienced laboratory personnel False-negative can occur if bacterial species are grown under conditions below the detection limit of selective media Some fastidious, stressed, viable but non-culturable bacteria in biofilms lead to false-negative results If PI doesn't penetrate the dead cell's membranes, they are falsely determined as viable cells	Vandecandelaere et al. (2012) and Xu et al. (2012)
Viability assessment by SYTO 9/propidium iodide (PI) staining	Observing the biofilm structure	Stained biofilms can be visualized and characterized by a microplate reader, flow cytometry, or CLSM	Combinations of SYTO 9 and PI may cause high background signals, crosstalk, and rapid photobleaching It is difficult to measure total number of cells in Gram-negative bacteria's biofilms	Ong et al. (2019) and Hofmann et al. (2012)
Assessment of the total biomass by crystal violet (CV) staining assay	Measuring the total biomass of biofilms		Unable to quantify the actual number of viable cells There is no standardized protocol Variation of the absorbance signals between bacterial species	Paytubi et al. (2017) and Merritt et al. (2005)
<i>Biofilm measurement by metabolic activity</i>				
MTT staining assay	Measuring metabolic activity of biofilms	Simple, fast, and high reproducibility	Require the cell lysis before reading optical density Components of growth media influence bacterial reduction of MTT to formazan Assay score falsely increases if the outer membrane is damaged	Traba and Liang (2011) and Chusri et al. (2013)
XTT staining assay	Measuring metabolic activity of biofilms	Directly measure the amount of formazan Perform an antibiotic susceptibility test of intact biofilms	Poor linear relationship between the colorimetric signal and the bacterial concentration in biofilms Require optimization of standard curve between the formazan product absorbance and the number of viable cells Signal intensity can be influenced some bacteria contain significant amount of intracellular salts	Gabrielson et al. (2002), Adam et al. (2002), and She et al. (2016)
Resazurin (Alamar Blue) staining assay	Measuring metabolic activity of biofilms	Fast and cost effective High sensitivity to detect low levels of viable bacteria Good correlation between the number of bacterial cells and the fluorescent signals	The rates of resazurin metabolization are different depending on the bacteria Incubation times required for the bacteria are different in multi-species biofilms	Paytubi et al. (2017) and Bandeira Tde et al. (2013)
ATP bioluminescence assay	Measuring metabolic activity of biofilms	Fast and easy to perform Sensitive to detect low metabolic activity It is not disturbed by fluorescent substances	It is not suitable to quantify biofilms if ATP is not fully extracted or biofilms are grown for extended periods of time	Stiefel et al. (2016) and Wilson et al. (2017)

bound CV is solubilized by either ethanol, a mixture of ethanol and acetone, glacial acetic acid, or dimethyl sulfoxide (Merritt et al., 2005). Finally, the absorbance of the solubilized CV is determined using a spectrophotometer at 530–600 nm. Some researchers have also fixed *Staphylococcus* species and *Mannheimia haemolytica* biofilm cells with either absolute ethanol, methanol or heat treatment at 60–80 °C to prevent widespread detachment of biofilms prior to dye staining (Thomas et al., 2015; Dassanayake et al., 2020; Stepanovic et al., 2000). Since this dye stains negatively charged molecules and anionic proteins in both viable and dead cells in biofilms without specificity, it is not possible to quantify the actual number of viable cells (Veloz et al., 2019). Furthermore, there is no standardized protocol for CV staining, so there are variations between the results obtained from different studies (Stepanovic et al., 2000). Peeters et al. reported that quantification of *P. aeruginosa* biofilms using CV staining failed to provide consistent results and the absorbance signals of *P. aeruginosa* were significantly lower than the signals of *Burkholderia cenocepacia*, *Staphylococcus aureus*,

Propionibacterium acnes and *C. albicans* (Peeters et al., 2008a). Also, CV staining was not as accurate as tetrazolium salts, such as 2,3,5-triphenyl-tetrazolium chloride (TTC), when the minimum biofilm inhibitory concentrations (MBIC) of amikacin and cefixime against *P. aeruginosa* were determined (Sabaeifard et al., 2014).

Several researchers have used safranin, Congo red, or calcofluor white instead of CV to measure total biofilm biomass. Safranin is not toxic and binds to negatively charged molecules of biofilm, but is less utilized for biomass assessment and shows a lower optical density than CV (Ommen et al., 2017). Safranin has been applied to study the effects of antibiotics (naphthoquinone-plumbagin), vitexin (polyphenolic group of phytochemicals), rhamnolipid (RL-SS14), brominated furanone, epigallocatechin gallate, short-chain fatty acids, phage, extracts of *Artemisia princeps*, *Lonicera caerulea* var. *emphyllcalyx*, essential oils of *Chamaecyparis obtusa*, *Chrysanthemum boreale*, *Origanum vulgare* subsp. *hirtum*, *Curcuma longa*, cold atmospheric plasma, electrolyzed water, rifampin-loaded hydrogel, and implant materials (metal alloys, zirconia, polyetherketoneketone, and titanium) on biofilm formation in various bacteria (Gupta et al., 2017; Das et al., 2016; Sen et al., 2020; Castillo et al., 2015; Yoneda et al., 2013; Cano et al., 2021; Yang et al., 2019; Minami et al., 2019; Kim et al., 2015b; Kim et al., 2015a; Schillaci et al., 2013; Lee et al., 2011; Ulu et al., 2018; Sun et al., 2012; Cahill et al., 2021; Zeller et al., 2020). Ommen et al. compared biofilm formation of *S. aureus*, *S. epidermidis*, and *P. aeruginosa* using CV and safranin as staining dyes (Ommen et al., 2017). They recommended safranin staining for biofilm measurements, as safranin staining is more reproducible, less toxic and easier to use than CV. Congo red has been used to measure the production of amyloid fibers and adopted to determine the amounts of polysaccharides and cellulose that comprise biofilms (Bely and Makovitzky, 2006). Because of its high background signal, Congo red has been employed to stain chronic wound biofilms with large amounts, rather than small amounts, of biofilms (Stiefel et al., 2016). Also, it has been added to agarose and utilized to measure biofilms formed on agar plates (Kaiser et al., 2013). Calcofluor white is a non-specific fluorochrome that binds to (1–3) and (1–4)- β -linked carbohydrate linkages (Nett et al., 2011). It has been predominantly used to study biofilm structures of *C. albicans* as well as *Campylobacter jejuni*, *Pseudomonas* species, *S. enterica*, and *Staphylococcus* species (Daher et al., 2011; Alfatah et al., 2017; Drozd et al., 2014; Quatrin et al., 2017; Gonzalez-Machado et al., 2018; Grecka et al., 2020).

Biofilm measurement by metabolic activity

MTT staining assay

MTT is a yellow soluble tetrazolium salt that is reduced to an insoluble purple crystal by viable cells (Sliwka et al., 2016). The MTT staining assay has been frequently used to investigate cell proliferation and cytotoxicity in human cells, and applied to quantify viable cells in biofilms (Fig. 6) (Traba and Liang, 2011). It is simple, takes a short time to analyze, and provides reproducible results (Table. 1) (Chusri et al., 2013). However, Manavathu et al. reported that it is difficult to differentiate the contribution of bacterial cells to the reduction of MTT in antimicrobial susceptibility tests of dual-species biofilms composed of *Aspergillus fumigatus* and *P. aeruginosa* to voriconazole and cefepime (Manavathu et al., 2014). Moreover, components of growth media, including amino acids, especially histidine, greatly influence bacterial reduction of MTT to formazan (Benov, 2019). The results are not trustworthy when evaluating the susceptibility of a new antimicrobial agent that affects the outer membrane integrity of Gram-negative bacteria with MTT because the assay score falsely increased when the outer membrane is damaged (Grela et al., 2015).

XTT staining assay

XTT is a yellow tetrazolium salt that is reduced to water-soluble formazan by enzymes of the respiratory chain of bacteria and the succinate dehydrogenase of fungi (Cerca et al., 2005). The XTT staining assay has been broadly employed for evaluating bacterial viability, not only in planktonic cells but also in biofilm cells of both bacteria and yeasts (Fig. 7) (Gabrielson et al., 2002; Adam et al., 2002; She et al., 2016). It has also been employed more in biofilm studies than the MTT staining assay. A large number of researchers have worked on the inhibition of fungal biofilms by anti-fungal agents, or the interaction of mixed biofilms of fungi and Gram-negative or Gram-positive bacteria (Pierce et al., 2008). While MTT staining requires the lysis of cells with dimethyl sulfoxide before reading optical density, XTT can be directly measured as the amount of orange/yellow formazan byproduct (Table. 1) (Costa-Orlandi et al., 2017). Furthermore, XTT staining of intact biofilms for antibiotic susceptibility can be performed without damaging the biofilm structure (Kuhn et al., 2002). As various bacterial species may metabolize XTT differently, XTT can have a poor linear relationship between the colorimetric signal and the bacterial concentrations in biofilms (Alonso et al., 2017). Therefore, it is necessary to optimize the standard curve of the formazan product absorbance with the number of viable cells before analyzing

Fig. 7 Human serum inhibits *Staphylococcus epidermidis* ATCC35984 biofilm formation. Overnight culture was treated with 0–100% HS at 37 °C for 24 h. The volume of biofilm was determined by both the CV assay and by the XTT assay. CV, crystal violet. Reprinted with permission from She P, Chen L, Qi Y, Xu H, Liu Y, Wang Y, Luo Z, and Wu Y (2016) Effects of human serum and apo-Transferrin on *S. epidermidis* RP62A biofilm formation. *MicrobiologyOpen* 5(6):957–966. <https://doi.org/10.1002/mbo3.379>.

biofilms. In addition, depending on the biofilm growth conditions, the signal intensity of XTT can be affected since some bacteria contain significant amounts of intracellular salts (Silva et al., 2021).

Resazurin (Alamar Blue) staining assay

The resazurin staining assay uses the reduction by bacterial viable cells of the blue, non-fluorescent, and non-toxic dye, resazurin, to pink, fluorescent resorufin to assess the viability of biofilms (Fig. 8) (Paytubi et al., 2017; Bandeira Tde et al., 2013). Compared to MTT and XTT staining assays, not only does the assay take less time to perform, but it also is cost effective and has a good correlation between the number of bacterial cells in biofilms and the fluorescent signal (Table. 1) (Van den Driessche et al., 2014). In addition, it is highly sensitive and can detect low levels of viable bacteria, up to 1000 colony forming units/biofilm. Depending on the bacteria, the rates at which resazurin is metabolized are different (Sandberg et al., 2009). Also, in multi-species biofilms, the incubation times required for the bacteria are different. Peeters et al. quantified biofilms of *P. aeruginosa*, *B. cenocepacia*, *S. aureus*, *P. acnes* and *C. albicans* in 96-well microtiter plates by CV, Syto 9, XTT, resazurin, and other staining methods and found that the resazurin staining assay was better than others in terms of detection limit, reproducibility, cost, and time (Peeters et al., 2008a). Some investigators reported that combinations of resazurin and CV, or resazurin and dimethyl methylene blue, in staining assays could provide better information than a single assay for *S. aureus* biofilms (Skogman et al., 2012; Tote et al., 2008).

Adenosine triphosphate (ATP) bioluminescence assay

ATP is the central metabolite that acts as an energy transfer molecule in all metabolically active organisms (Kumon et al., 1995). Upon cell death, ATP in cells is quickly broken down by ATPase (van der Kooij, 1998). In the presence of luciferase extracted from the firefly *Photinus pyralis*, a substrate, luciferin, is activated with ATP to produce luciferyl adenylate and pyrophosphate (Nikawa et al., 2003). Then, the luciferyl adenylate reacts with oxygen to generate oxyluciferin and adenosine monophosphate. The oxyluciferin in an excited state comes back to the ground state and emits a luminescent light that can be detected by a luminometer and expressed in relative light units. The ATP assay is easy to execute, sensitive enough to detect microorganisms of low metabolic activity, and can be detected within 20 s (Table. 1) (Wilson et al., 2017). In the quantification of viable sessile cells of *P. aeruginosa* and *S. aureus* after treatment with cleaning agents, the luminescent signal of the bacterial samples with sodium chloride showed high sensitivity, 1000 times higher than that of the cell-free BacTiter-Glo reagent solution (Stiefel et al., 2016). The ATP assay is not disrupted by fluorescent substances and can be used to quantify viable cells in both planktonic and sessile cells (Wilson et al., 2017). However, it is not suitable to quantify biofilms if ATP is not fully extracted or biofilms that are grown for extended periods of time (Gonzalez-Rivas et al., 2018). The ATP bioluminescence assay has been used primarily to evaluate biofilm formation in drinking water systems, as well as to monitor biofilm removal from medical products, such as endoscopes and orthopedic implants, and to test anti-biofilm activity of antimicrobial agents, nanoparticles, essential oils, and ultraviolet light emitting diodes (Lehtola et al., 2004; Luo et al., 2020; Karpanen et al., 2008; Jothiprakasham et al., 2017; Hendry et al., 2009; Gora et al., 2019).

Biofilm detection by microscopical techniques

Conventional light microscopy

A light microscope employs visible light and a magnifying lens to observe tiny objects that cannot be seen with the naked eye and has long been used as an essential tool for investigating bacteria (Relucenti et al., 2021). Early microscopes magnified up to 275 times, but technological advances have made it possible to magnify up to 1000 times (de Boer et al., 2015). Light microscopy is generally used to study bacterial cells larger than 0.5 μm (de Boer et al., 2015). Observing bacteria using light microscopy is not expensive, it is easy to prepare and observe samples, and it is possible to observe a large area of viable cell cultures for extended periods of time (Table. 1) (Relucenti et al., 2021). Furthermore, light microscopy can visualize sessile cells after staining with crystal violet or other dyes and does not require other advanced microscopy techniques, but it has difficulty in enumerating the total numbers of bacteria in biofilms (Fig. 9) (Pelzer et al., 2012; Sowndarya et al., 2020). Conventional light microscopes have the disadvantage of not being able to measure small components of bacterial cells or details of the biofilm structure, as they have a lower resolution and magnification than electron microscopes (Azeredo et al., 2017). Optical microscopy has evolved into a technique capable of assessing static images of biofilms and evaluating dynamic characteristics of molecules present in biofilms (Sankaran et al., 2018). For example, fluorescence microscopy exploits the ability of fluorescent dyes to emit visible light at specific wavelengths when UV light is used (Sanderson et al., 2014). Epifluorescence microscopy, one of the most widely used techniques, offers higher resolution, shows detailed architecture of biofilms cultured on opaque surfaces, such as metal, and can be used to count viable bacteria in biofilms (Carneiro et al., 2009). Diverse color imaging has become possible as the technology for detecting fluorescent proteins and labels, along with filter and camera technology, have progressed (Xu et al., 2005). While acridine orange binds both DNA and RNA and can be used for studying biofilms on food contact surfaces, 4',6-diamidino-2-phenylindole binds to DNA and can be used to count the total number of cells in biofilms (Poimenidou et al., 2009; Wirtanen et al., 2001). Additionally, the viability of monolayer biofilms of Gram-positive and -negative bacteria may be assessed by epifluorescence microscopy after staining bacteria with SYTO 9 and PI (Rosenberg et al., 2019). Green fluorescent protein (GFP), a good marker to label bacterial cells in biofilms without destroying them, can be detected by blue light irradiation (Yoshida and Kuramitsu, 2002). GFP-labeled bacteria have been used to investigate survival and spatial distribution in biofilms (Hentzer et al., 2002; Banning et al., 2003). Hiraki et al. adopted Alcian blue, a copper phthalocyanine cationic dye, to visualize and quantitatively measure the extracellular polysaccharide within biofilms produced by bacteria attached to the surface of the aquatic macrophyte *Phragmites australis* (Hiraki et al., 2009).

Confocal laser scanning microscopy (CLSM)

Unlike conventional light microscopy, CLSM makes use of a laser to illuminate and scan biological samples, rejects out of focus fluorescent images, and acquires images from continuous sections of thick biofilms (Fig. 4) (Ong et al., 2019; de Carvalho and da Fonseca, 2007). It has become the most useful microscopy to explore spatial organization of biofilm architecture. Since CLSM software can include a multi-parametric quantitative data set of fluorescence intensities with each image, it can determine viable and dead cell numbers of bacteria, identify bacterial species in polymicrobial biofilms, and perform horizontal and vertical optical sectioning of three-dimensional biofilms (Table. 1) (Kleine et al., 2019). Some researchers have studied the effects of antimicrobial agents, such as epigallocatechin-3-gallate, amphotericin B, voriconazole, flucytosine, caspofungin, and chitosan-coated iron oxide nanoparticles on the viability of sessile cells using CLSM (Vidigal et al., 2014; Bojsen et al., 2014; Shi et al., 2016). Bao et al. employed CLSM to demonstrate movement in the spatial arrangement of *Porphyromonas gingivalis*, *Fusobacterium nucleatum*, and *Treponema denticola* within polymicrobial dental biofilms (Bao et al., 2014). Furthermore, when studying the interactions between EPS and extracellular DNA or between EPS and silica nanoparticles, three-dimensional image analyzes of CLSM made it possible to

analyze structural parameters, including thickness, biovolume, and surface coverage (Peng et al., 2020; Hiebner et al., 2020). FISH identifies bacterial species within biofilms by using oligonucleotide probes labeled with fluorescent dyes (Thurnheer et al., 2004). The probes bind 16S rRNA, which has both highly conserved and variable DNA sequences, to discriminate members of the microbial population (Thurnheer et al., 2004). Combining CLSM and FISH systems has made it possible to investigate the effect of a single bacterium on biofilms formed by another bacterium or mixed bacteria. This combination can also be used to measure the viability of a target bacterial species in multispecies biofilm samples and to detect bacterial species, quantities, structures and polymicrobial interactions in biofilms collected from human tissues and environmental samples (Romero-Lastra et al., 2019; Thornton et al., 2011; Elifantz et al., 2013; Klug et al., 2016).

Scanning electron microscopy (SEM) and transmission electron microscopy (TEM)

EM has been used to produce high resolution images in biomedical science, material science, semiconductor inspection, and forensic investigations (Cazaux, 2005). SEM provides an image of topography and composition by scanning the sample surface with an electron beam (Fig. 10 and Table. 1) (Stokes, 2003). Secondary electrons (low-energy electrons) are used to show morphology and topography of the sample surface, and backscattered electrons (high-energy electrons) show spatial distribution by atomic number contrast (Stokes, 2003). The magnification and spatial resolution of SEM are from 20 to 30,000 X and from 50 to 100 nm, respectively (Cazaux, 2005). Since biofilms are non-conductive, they must be fixed with glutaraldehyde, dehydrated, and sputter coated before being observed with SEM (Weber et al., 2014). While the drying step of SEM can damage biofilm shape, variable pressure SEM (VPSEM), environmental SEM (ESEM) and cryo-SEM can better protect biofilm shape (Relucenti et al., 2021).

TEM uses an electron beam penetrating through a very thin specimen (Jublot and Texier, 2014). TEM samples are prepared by slicing the sample into thin sections less than 100 nm and staining with uranyl acetate and lead citrate (Fig. 11) (Graham and Orenstein, 2007). While SEM provides an image of the three-dimensional structure of biofilms, TEM creates a two-dimensional image with a resolution of approximately 0.2 nm of the components, such as nucleic acids and proteins, inside an individual bacterial cell, showing the comprehensive morphology and structure of the bacteria that make up biofilms (Table. 1) (DeQueiroz and Day, 2007). Compared to TEM, SEM not only costs less, it also requires less time to image and less labor for sample preparation, and it allows larger samples to be inspected (Walker et al., 2001). On the other hand, TEM provides higher resolution, crystallographic and atomic data, and enables more detailed characterization, but it needs highly experienced technicians for sample preparation (Chuo et al., 2018). SEM and TEM have been widely used to study biofilms together with the CLSM technique. The three combined techniques have been adopted to investigate the interaction of bacterial species in mixed biofilms, the

Fig. 11 TEM image of *Campylobacter jejuni* 11,168 biofilm grown on a stainless steel coupon. The scale bar in the image corresponds to 1.0 μm .

morphological alteration of biofilm structure after treatment with antimicrobial agents (peptides, magnolol, fosfomycin, and nanoparticles), the irrigation effect on root canal, the difference in biofilm morphology in relation to nutrient availability, and the prevalence and distribution of biofilms in indwelling catheters (Ramirez Granillo et al., 2015; Geng et al., 2018; Behbehani et al., 2017; Monden et al., 2002; Rajivgandhi et al., 2020; Mohammed et al., 2017; Wang et al., 2017; Gorman et al., 1994; Pronk et al., 2017).

Atomic force microscopy (AFM)

AFM is a powerful approach to provide three-dimensional images of viruses, bacteria, human cells, biomaterials, polymers, semiconductors, metals, ceramics, and glasses from the nanometer to micrometer scale, and quantitative information, including elastic properties and adhesion forces (Vahabi et al., 2013). It employs a sharp probe to scan the sample surface and analyzes the sample image without damaging it under ambient conditions, but large-scale samples are difficult to analyze using AFM (Deng et al., 2018; Louise Meyer et al., 2010). Furthermore, biological samples in liquid move freely during AFM imaging, so they must be analyzed after immobilizing the sample (Louise Meyer et al., 2010). AFM has been frequently used to obtain three-dimensional surface structures of biofilms and to quantify the adhesion forces of bacterial biofilms formed on various surfaces of biomaterials (Fig. 12, Table 1) (Handorf et al., 2019; Wang et al., 2020; Merghni et al., 2017). It has been also used to analyze thickness and EPS quantity of sessile cells by measuring the height and roughness after biofilm treatment with antimicrobial agents or nanoparticles (Salunke et al., 2014; Chatterjee et al., 2014). Additionally, to characterize the effect of growth conditions (nutrient components, pH, and flow conditions), antimicrobial agents (chlorhexidine and antimicrobial peptides), and viscoelastic characteristics of the biofilm surface have been quantitatively measured by AFM (Martin-Rodriguez et al., 2014; Ho et al., 2013; Schofield et al., 2007; Rodgers and Murdaugh, 2016; Quiles et al., 2016; Formosa-Dague et al., 2016; Lau et al., 2009).

Fig. 12 Atomic force microscopy (AFM) images of the MiniMIP-treated biofilms and untreated controls. The left side shows the topographic image and the right side shows the error-signal image of the same spot. (A) Untreated control; (B) 30 s plasma treatment time; (C) 60 s plasma treatment time. The images were acquired in contact mode with a cantilever spring constant of $k = 0.1\text{--}0.6\text{ N/m}^2$ and a frequency of 0.4 Hz, the set point at 8 N/m^2 and an area of $20\text{ }\mu\text{m}^2$. Reprinted with permission from Handorf O, Schnabel U, Bösel A, Weihe T, Bekeschus S, Graf AC, Riedel K, and Ehlbeck J (2019) Antimicrobial effects of microwave-induced plasma torch (MiniMIP) treatment on *Candida albicans* biofilms. *Microbial Biotechnology* 12(5):1034–1048. <https://doi.org/10.1111/1751-7915.13459>.

Conclusion

Bacterial biofilms are complicated assemblages of proteins, lipids, polysaccharides, and lipopolysaccharides, and usually contain many different bacterial species. Since biofilm cells possess different characteristics from planktonic cells, there are many limitations that restrict the application of methods developed for planktonic cells to detect biofilm cells. Although biofilms cause serious problems in the human body (pulmonary and dental tissues) and medical devices (urinary and central venous catheters), the usual methodologies performed in clinical laboratories in hospitals can only detect planktonic bacteria. This article describes methods for detecting biofilms with the advantages and disadvantages. Investigation of biofilm cells requires a variety of approaches and accurate interpretation, from the most basic method of determining the total number of viable cells to advanced microscopy methods that reveal three-dimensional structures. Advanced in vitro and in vivo models and detection methods will be necessary to accurately and rapidly detect and investigate biofilms.

Glossary

Apheresis/plasmapheresis Method of obtaining one or more blood components—for plasmapheresis the blood component is plasma—by machine processing of whole blood, in which the residual components of the blood are returned to the donor during or at the end of the process.

Blood establishment Any structure or body that is responsible for any aspect of the collection and testing of human blood or blood components, whatever their intended purpose.

Blood-borne viruses Viruses with a viremic phase, i.e., virus detectable in blood/plasma. The major blood-borne viruses of concern for plasma-derived medicinal products (PDMPs) are viruses causing regularly a persistent infection as human immunodeficiency virus (HIV), hepatitis C virus (HCV), and hepatitis B virus (HBV).

CAPA Corrective action and/or preventive action.

Change control A formal system by which qualified representatives of appropriate disciplines review proposed or actual changes that might affect the validated status of facilities, systems, equipment or processes. The intent is to determine the need for action that would ensure and document that the system is maintained in a validated state.

Computerized system A system comprising the input of data, electronic processing and the output of information to be used either for reporting, automatic control or documentation.

Donor deferral Suspension of the eligibility of an individual to donate blood or blood components; such suspension being either permanent or temporary.

EDQM European Directorate for the Quality of Medicines & HealthCare.

EMA European Medicines Agency (formerly EMEA: The European Agency for the Evaluation of Medicinal Products).

FDA, CBER Food and Drug Administration, Center for Biologics Evaluation and Research (at US Department of Health and Human Services).

First time donor (First time tested donor) Person never donated either blood or plasma (person whose blood/plasma is tested for the first time for infectious disease markers (with or without donation)).

GMP Good Manufacturing Practice.

Incidence Rate of newly acquired infection identified over a specific time period in a defined population; commonly, for blood transmissible infections the positivity rate in NAT assays ("NAT only," i.e., serological assays are non-reactive) correspond to incidence.

Inventory hold Physical isolation of plasma over at least 60 days after collection in order to retrieve and interdict a donation based on post-donation informations as tested reactive in infectious disease markers in subsequent donations and further information about high risk behavior; otherwise, the donation is released for pooling after (at least) 60 days.

NAT Nucleic acid amplification technique (e.g., PCR: polymerase chain reaction or TMA: transcription-mediated amplification).

PDMP Plasma-derived medicinal product.

Prevalence Frequency of infection identified (including past and recent infections) at a specific point in time or over a specific time period in a defined population; commonly, for blood transmissible infections the positivity rate in serological assays correspond to prevalence.

Qualification Part of validation and meaning the action of verifying that any personnel, premises, equipment or material works correctly and delivers the expected.

Quality assurance All the activities from blood collection to distribution made with the object of ensuring that blood and blood components are of the quality required for their intended use.

Quality control Part of a quality system focused on fulfilling quality requirements.

Quality management The co-ordinated activities to direct and control an organization with regard to quality at all levels within the blood establishment.

Quality system The organizational structure, responsibilities, procedures, processes, and resources for implementing quality management.

Quarantine Physical isolation of plasma and release for further processing only when after a defined time period post collection, the donor is tested again nonreactive for infectious disease markers (commonly 4 months when donations are NAT tested).

Repeat donor/regular donor (repeat tested donor) Person donated before blood or plasma in accordance with minimum time interval (person whose blood/plasma has been tested previously for infectious disease markers).

Traceability The ability to trace each individual unit of plasma from the donor to its final destination, whether this is a recipient, a manufacturer of medicinal products or disposal, and vice versa.

Window period During the window period a test method is unable to detect a recent infection (with viremia), commonly because antibodies are not yet produced and/or detectable by a serological screening assay. Occasionally, a window period is also estimated for antigen and NAT testing when the virus concentration in blood/plasma is below the methods' limit of detection for antigen or NAT screening assays.

Introduction

Plasma-derived medicinal products are required to treat many diseases, especially rare diseases or conditions. In the past, they have been used primarily in critical care settings (e.g., human serum albumin) and for the treatment of inherited diseases (e.g., hemophilia A and B). Nowadays, the majority of plasma collected is required to manufacture immunoglobulins (polyvalent intravenous immunoglobulins—IVIG and subcutaneous immunoglobulins—SCIG) predominantly for the treatment of primary immunodeficiency (PID), polyneuropathy (CIDP), and idiopathic thrombocytopenic purpura (ITP); the treatment of secondary immunodeficiency caused, e.g., by chemotherapy, auto-immune disorders and other immune deficiencies is also treated by immunoglobulins. Furthermore, pathogen infections are treated by these polyvalent immunoglobulins; for defined pathogens or their toxins and for further defined conditions hyperimmune globulins are administered, e.g., against rabies, hepatitis A and B, tetanus, diphtheria, shingles (varicella zoster virus), cytomegalovirus, as well as anti-D immunoglobulin (Rho(D) immune globulin (to prevent in pregnancy RhD (rhesus) isoimmunization in RhD negative mothers). Further plasma-derived proteins commercially extracted from plasma are, e.g., immunoglobulin M, von Willebrand factor, fibrinogen, prothrombin complex concentrate, factor VIIa, factor X, factor XI, factor XIII, and the inhibitors alpha-1-proteinase inhibitor, C1-esterase inhibitor, and antithrombin (ATIII).

Depending on the regulations in different areas in the world and the economics of blood/plasma collection, recovered plasma and source plasma may be used in different proportions to produce plasma-derived medicinal products (PDMP). Recovered Plasma (also call Fresh Frozen Plasma when it was originally intended for transfusion) is the plasma obtained after processing of whole blood into red cell and platelet concentrates and plasma, while Source Plasma is the plasma obtained by apheresis during which red cells, platelets and white cells have been returned to the donor and the collected plasma is intended for further manufacture into injectable or diagnostic products. As the volume of a recovered plasma donation is approx. 280 mL and strict restriction regarding interdonation intervals and total donations per year exist to protect the donor's health (e.g., six donations per year for male donors and four donations for female donors in Europe (EDQM, 2020)) a Recovered Plasma donor can provide approx. 1.5 L of plasma per year. In contrast, Source Plasma donors can donate up to 104 times per year in the United States and up to 40 times per year in Europe, resulting in almost 90 L plasma per donor in the United States and approximately 25 L in Europe (Simon et al., 2009). In other areas of the world different regulations may apply; for instance, in China only source plasma is allowed to be fractionated and the interdonation interval is considerably longer (14 days). Source plasma donations are required to meet the demand for PDMPs by patients with rare diseases or conditions.

Fig. 1 shows the worldwide plasma protein market 2016 documenting that most of the products are polyvalent immunoglobulins (47.3% of the market is due to polyvalent immunoglobulins applied either intravenously (IVIG) or subcutaneously (SCIG)). The value of the total market in 2016 is US\$ 21,174 million (Marketing Research Bureau Inc. (MBR), Orange, Connecticut, United States).

In order to manufacture these products, collection of a large amount of plasma is essential. Depending on the regulation in different areas in the world and the economics of blood/plasma collection, recovered plasma (derived from whole blood donations) and source plasma (collected by apheresis), may be used in different proportions. Fig. 2 shows the amount of plasma collected worldwide in 2015, a total of 48,744,000 L; most of the plasma for fractionation—to meet the need of patients—is source plasma (81% of all plasma collected). The majority of plasma for fractionation (recovered and source plasma) collected worldwide is derived from donors in North America, primarily United States. Considering only source plasma (collected by plasmapheresis), in Middle East/Africa and Latin America no source plasma is collected, whereas approximately 43% in Europe, 81% in Asia and Pacific, and 94% in North America of all plasma collected is source plasma. Approximately three quarter of all source plasma collected worldwide is collected in North America (primarily in the United States).

The selection and control of the starting material of PDMP, the plasma pool for fractionation, is a major factor in the quality assurance of these products. This process includes the collection process itself, for example, the careful selection of plasma collection facilities (donor centers), which are audited by the fractionator using the plasma for the production of PDMPs and are inspected by the relevant authorities. All donors have to be healthy, documented in a physical examination, and have to provide answers to a predefined questionnaire at the time of each donation. The questionnaire is used to identify any donors who could pose a risk, either regarding his/her own health or the health of recipients of PDMPs, in terms of transmitting pathogens, and to reject their donation and defer the donor, depending on the risk, either temporarily or indefinitely. Further-on, each donation is tested for a pre-defined panel of blood-borne viruses in line with regulatory requirements in place where the plasma is collected and the PDMP manufactured; only donations non-reactive (negative) can be combined to the plasma pool for fractionation. Finally, each plasma pool, the starting material of PDMPs, is tested in most countries for the presence of blood-borne viruses and released for further processing only when non-reactive; testing is required e.g., for products marketed in Europe to be compliant with the Ph. Eur.

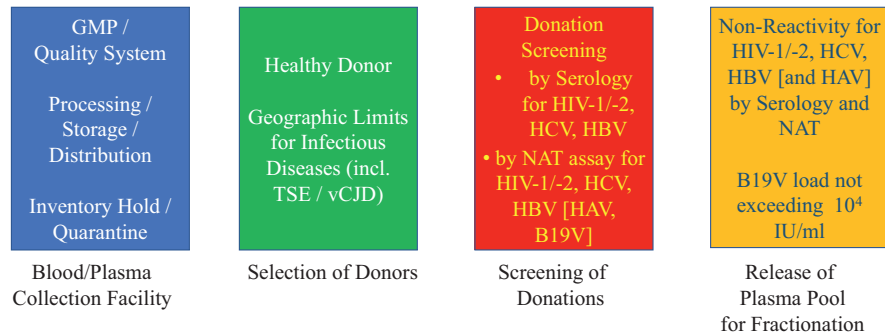

Fig. 3 Measures commonly implemented to mitigate risk of a high virus load in the plasma pool for fractionation to manufacture plasma-derived medicinal products by four pillars—blood/plasma collection facility, selection of donors, screening of donations, and release of plasma pools for fractionation—with specific criteria for each pillar. *TSE*, transmissible spongiform encephalopathy; *vCJD*, variant Creutzfeldt-Jakob disease; *HIV-1/-2*, human immunodeficiency virus type 1 and 2; *HCV*, hepatitis C virus; *HBV*, hepatitis B virus; *HAV*, hepatitis A virus; *B19V*, human parvovirus B19; *NAT*, nucleic acid amplification technique.

Monograph for Human Plasma for Fractionation and with any requirements for particular products for which Ph. Eur. Monographs exist. In order to manufacture PDMPs with a high margin of safety regarding viruses (and other pathogens), in the manufacturing process of these products dedicated virus reduction steps are incorporated with effective virus reduction capacities (this last aspect of the production of PMDPs is not covered in this chapter). A rigorous traceability system has to be in place to follow each donation to a finished product batch and backwards from a finished product batch to a donation and, thus, to a donor; this is especially relevant for pharmacovigilance covering adverse drug reactions.

Fig. 3 depicts the measures taken to manufacture PDMPs with a high margin of safety regarding blood-borne viruses considering the blood/plasma collection facility, the selection of donors, the screening of donations and the release of plasma pools for fractionation for further manufacturing.

Measures implemented in blood/plasma collection facility

Each blood establishment (blood/plasma collection facility) has to develop and maintain a quality system based on GMP principles. All quality objectives as quality planning, quality control, quality assurance and quality improvements have to be implemented in order to meet predefined specifications. These GMP topics include quality management, personnel, documentation, premises and equipment, qualification and validation, materials management, contract manufacturing, and complaints and recalls (WHO, 2011). Therefore, all manufacturing processes have to be clearly defined by policies and standard operating procedures that are systematically reviewed in the light of experience and are shown to be capable of consistently manufacturing blood/plasma of the required safety and assured quality that comply with their respective specifications. Equipment and reagents have to be qualified and processes and methods validated prior to use in the manufacture of products intended for transfusion or further manufacturing. Establishing a reliable quality assurance system for the whole chain of blood/plasma collection, processing and distribution of blood components is of eminent importance.

GMP is the part of quality assurance that ensures that blood products are consistently produced and controlled to the quality standards appropriate to their intended use, as required by predefined specifications. Quality assurance functions is involved in all quality-related matters as personnel and organization, documentation system, computerized systems/electronic information system, premises and equipment, materials, qualification and validation, storage and transport, record keeping, documentation and review of results, change control, corrective and preventive actions (CAPA), complaints, recalls and audits as well as contract between blood establishment and fractionator. All these GMP related topics are relevant to diminishing risks inherent in any blood establishment operation as preventing contamination (including cross-contamination), mix-ups and executing labeling, component separation and freezing within a pre-defined interval after completion of donation to a temperature below -30°C within 1 h as well as storage and transportation according to regulation by authorities (commonly at below -25°C); thus, disease transmission or other unexpected adverse outcomes resulting from the use of blood/plasma products can be substantially diminished by appropriately controlled processes and procedures.

Besides such general GMP requirements further specific requirements for blood/plasma collection facilities are relevant: For any materials potentially impacting the quality and safety of the product, i.e., primary packaging materials, equipment, additive solutions, starting materials and blood and blood components, detailed specifications must be in place and all containers must be labeled with relevant information to ensure traceability at each stage of plasma production. Blood/plasma has to be approved for release for further processing by an authorized person, preferably supported by validated computerized systems. The specifications for release must be defined, validated, and documented. Donations from a repeat tested donor have to be compared with previous records of that donor and the release of blood/plasma has to be blocked until all relevant information is available. When a donation

is not acceptable for release to manufacture PDMPs due to, e.g., reactivity in assays for blood borne viruses, it may be used—properly labeled—however, for research purposes as, e.g., a source for diagnostic assays. Based on defined specifications, e.g., reactivity in HIV, HCV, or HBV testing, any future donations from this donor have to be blocked (the donor has to be deferred indefinitely from further donating). Inventory hold allows the retrieval of plasma units tested non-reactive (negative) for virus markers when a subsequent donation will be tested reactive (positive); therefore, this measure considerably protects plasma pools from containing window donations. Commonly, for source plasma an Inventory Hold of at least 60 days is implemented (e.g., PPTA, 2000a). National requirements (or voluntary measures by fractionators) may request more stringent measures, e.g., longer hold period and/or quarantine; for instance, in China the hold period is 90 days after collection and the donor has to be tested again. Only when these tests are non-reactive (negative), plasma collected 90 days before can be released for further manufacturing (Wang et al., 2018); this “Quarantine” of plasma is more stringent than “Inventory Hold” allowing the release of plasma after a storage time of, e.g., at least 60 days; post donation information as reactivity for infectious disease markers in subsequent donations within this Inventory Hold period results in the interdiction and destruction of the current donation and all donations stored in Inventory Hold. Therefore, a donation with a low virus load tested non-reactive according to quality assurance standards would not be used for pooling but would be retrieved and destroyed based on screening assay information of a subsequent donation. PPTA (Plasma Protein Therapeutics Association) has implemented a standard—QSEAL Inventory Hold Standard (PPTA, 2000a)—in addition to regulatory requirements; for all source plasma donations this standard applies to companies QSEAL certified together with the QSEAL Voluntary Standards “Controls on Incoming Plasma,” “Nucleic Acid Amplification Technology (NAT) Testing,” “Intermediates Purchased from an External Supplier,” “Recovered Plasma Specifications,” “Qualified Donor,” and “Viral Marker” (PPTA, 2000b). This PPTA Inventory Hold standard requires that all source plasma be held in inventory for at least 60 days from the time of collection such that post-donation information, e.g., reactivity in screening tests for HIV, HCV, and HBV in a subsequent donation, delayed admission of high-risk behavior or new information about international travel, could be addressed properly. The retrieval of non-reactive donations with a low virus load—below the limit of detection of a screening assay—is based commonly on results of NAT screening of subsequent donations. Fig. 4 shows the probability to detect a virus infection due to NAT testing of subsequent donations: considering the NAT window period of 15 days for HIV, 8 days for HCV and 35 days for HBV (EMA, 2016a), an HCV infection could be detected in a donation collected latest after approx. 1 week in the subsequent donation, an HIV infection in a donation collected approx. less than 2 weeks later than the non-reactive donation of an infected donor, and the detection of an

Fig. 4 Virus load [IU/mL] in a donation depending on the virus doubling time of HIV-1, HCV, and HBV prior to time of detection at day 0. Based on the virus doubling time, the NAT window period, and the sensitivity of the NAT assay (here, a minipool of 48 donations is considered) the probability to detect an infection in a subsequent donation to a donation tested non-reactive is highest for HCV and lowest for HBV.

HBV infection takes longer, up to approx. 5 weeks after infection. Therefore, an inventory hold period of at least 60 days mitigates efficiently the risk that a donation from an infected donor—below the limit of detection of the NAT screening assay—will be pooled to manufacture PDMPs. In Fig. 4, the limit of detection, based on the average 95% limit of detection for HIV-1, HCV, and HBV is 50 IU/mL, 10 IU/mL, and 5 IU/mL, respectively, using a NAT minipool of 48 donations. The virus doubling time was estimated at 20.5 h for HIV-1 (Fiebig et al., 2003), 10.8 h for HCV (Glynn et al., 2005), and 2.56 days for HBV (Biswas et al., 2003) and the viremic window period, i.e., the time to detect the infection by NAT is 15 days for HIV, 8 days for HCV and 35 days for HBV (EMA, 2016a). It has to be considered that pooling of samples of donations according to common procedures in screening laboratories (minipools of 24, 16, or 6 donations) will result in a higher virus load than disclosed in the product information for the Limit of Detection or Limit of Quantification and remain undetected correlating with the number of donations per minipool. In Table 1 the assumed virus load in different minipool systems is shown as well as the probability to detect an infection earlier by pooling less donations (compare Fig. 4 for virus doubling time). The interdonation interval, according to national regulatory agencies, of less than 7 up to 14 days will allow the identification of donations below the limit of detection for a certain virus stored in inventory hold due to the reactivity of a consecutive donation. These data also show that a quarantine of donations is not required to prepare a plasma pool for fractionation with no or only a minute load of blood-transmissible viruses when the epidemiology in the donor population is acceptable (compare topic “Epidemiology in Donor Population” and topic “Screening of Donations”).

First time tested donors, occasionally including test-seeking individuals, representing donors having more likely a higher rate of viral markers than regular/repeat tested donors as these donors have already gone through a selection or deferral process. Therefore, source plasma from first time tested donors is not used by most fractionators but only from “Qualified Donors” (PPTA, 2020). This PPTA IQPP standard defines the different donor populations: For source plasma donations, the first donation from an “Applicant Donor” (first time donor/potential donor) is initially quarantined. This quarantine can only be lifted when the donor has successfully passed a second medical history assessment and a second donation has been screened and shown to be free of the relevant transfusion-relevant viruses. These measures result in a healthy population of donors (known as “Qualified Donors”) committed to donating plasma. Source plasma from donors who have not reached the status of “qualified donors” is not processed for further manufacture and is, therefore, destroyed. Qualified donors who have not made a donation for a period of 6 months or more are considered to be applicant donors again. All donations are screened for viruses using currently licensed or approved (CE-mark) serological and nucleic acid amplification assays.

The Quality Assurance principles to be implemented cover all steps involved in the collection, preparation and testing activities reducing errors and technical problems, guard the donor selection criteria prior to each donation, assures the release of plasma, meeting the safety and quality specifications including the respective inventory hold/quarantine periods defined, and guarantee adequate documentation and full traceability for each donation.

Selection of donors

Selecting individuals for blood/plasma donations determines whether this person is in good health to ensure the health of both, donor and recipient of PDMPs, as much as possible.

When a donor arrives at the blood/plasma collection facility, evidence of his/her identity has to be provided and a donor identification system has to be established that positively identifies each donor and each donation; in addition, accumulated records and laboratory data are assigned to such donor (EDQM, 2020; CFR, 2020; WHO, 2011). Furthermore, information has to be provided to a (prospective) donor such that the donor can grant an informed consent prior to proceeding with the donation.

Protection of donor's health

Based on national regulatory guidance in the countries where the donation takes place, temperature, blood pressure, pulse, weight, and donor's age have to be within pre-defined limits. Total protein and/or immunoglobulin G concentration in a sample of a plasmapheresis donor should be monitored and, if not between normal limits, the donor is deferred from donation until the protein composition returns to acceptable levels. Long-term effects in source plasma donors in intensive plasmapheresis programs should be monitored for risks to the donor's health, e.g., association with citrate exposure and diminished IgG levels.

Table 1 Assumed virus load in a donation based on minipool testing.

<i>NAT screening assay: reactive at assumed virus load [IU/mL donation]</i>					
<i>Virus</i>	<i>In Fig. 4 (minipool of 48)</i>	<i>Minipool of 24</i>	<i>Minipool of 16</i>	<i>Minipool of 6</i>	<i>Single donation</i>
HIV	2400 (day 0)	1200 (day −0.9) ^a	800 (day −1.5) ^a	300 (day −2.6) ^a	50 (day −4.9) ^a
HCV	480 (day 0)	240 (day −0.5) ^a	160 (day −0.6) ^a	60 (day −1.4) ^a	10 (day −2.6) ^a
HBV	240 (day 0)	120 (day −2.6) ^a	80 (day −4.4) ^a	30 (day −7.7) ^a	5 (day −14.6) ^a

^aIncreased assay sensitivity/earlier detection of infection by reducing minipools size in days (bracketed) compared to testing minipools of 48 donations.

Commonly six whole blood donations per year for male donors and four whole blood donations for female donors with an interdonation interval of at least 2 months are acceptable to protect donors' health; national regulatory requirements have to be followed. For source plasma donations, a much higher rate of donations is allowed depending on the national regulatory requirements in place where the donation takes place: donors can donate up to 104 times per year in the United States and up to 40 times per year in Europe, resulting in up to 90 L plasma per donor in the United States and approximately 25 L in Europe (Simon et al., 2009). Due to the national regulatory requirements interdonation intervals and the amount of source plasma collected may differ between countries; e.g., in China approximately 25 times a donor can donate within a year, resulting in approximately 18 L plasma per donor calculated based on an interdonation interval of at least 14 days (Wang et al., 2018).

Hazardous occupations or hobbies, such as driving a bus or train or piloting, operating a crane, scaffolding and gliding, climbing and diving should only be performed after a sufficient recreation time, commonly not earlier than 12 h after donating, in order to avoid a risk to the donor and/or other people in the event of delayed vasovagal reaction following blood donation.

Pre-donation educational material has to be provided to a donor containing the essential nature of blood, the blood donation procedure, the aim of the medical assessment of the donor, and that a blood/plasma donation can not be drawn when carrying a risk to the recipient; furthermore, donors have to be informed on temporary and permanent deferral based on the medical examination and/or the results of donation screening as well as on self-deferral (EDQM, 2020). A thorough screening of each donor, i.e., a complete medical and physical examination is not feasible in reality; thus, the responsible physician at the blood establishment, or a trained physician substitute under the physician's supervision, will check the medical and physical health of the donor (including medication) based on a predefined questionnaire concerning medical history, general health, relevant risk factors as lifestyle and travel history, and on elementary laboratory tests.

The goal of such a questionnaire to be answered by the donor is to elicit relevant information on his/her health and lifestyle to be used as part of the screening process to establish the eligibility of a donor. To obtain relevant and consistent information about the donor's medical history and general health, such a questionnaire, together with educational materials and a medication deferral list, should be completed at each donation. Adaptation of the questionnaire to different donor categories such as first-time donor, repeat/regular donor or apheresis donor should be in place. An example of a questionnaire is provided by AABB (for whole blood donations) approved by the FDA to be used in blood establishments that collect blood and blood components; for repeat donors, an abbreviated donor history questionnaire may be used (FDA, 2020b). Also in Europe a questionnaire is strongly recommended to obtain information on the health and lifestyle of the donor that may adversely affect the safety of both, the recipient and the donor. A generic questionnaire is considered not appropriate, but a questionnaire should be developed according to local circumstances by the local (national) blood establishments (EDQM, 2020). Nevertheless, the principle and content of the questionnaires are comparable and elicit information from the donor regarding, e.g., his/her general health, previous blood donations, weight, serious illness, and hazardous occupation and hobbies.

Protection of recipient's health

Besides the health of the donor, the health of the recipient of a blood component donation and in this chapter, especially, of PDMPs is very important. Here, the capability to transmit blood-borne viruses (and, potentially, variant Creutzfeldt-Jakob disease (vCJD)) has to be assessed.

Blood-borne viruses, namely HIV—but also HCV and HBV—can be transmitted by sexual contacts; especially men who have sex with men (MSM) are infected by a range of pathogens (e.g., Soares et al., 2014). In several countries screening for syphilis is used (e.g., FDA, 2020c), although syphilis testing, as a surrogate marker for sexual risk behavior, has a low sensitivity and a low positive predictive value as a surrogate marker for detecting known transfusion-transmitted viruses as HIV, HCV and HBV (Zou et al., 2009).

In Europe, the most affected group for newly diagnosed HIV infections in 2012 were MSM accounting for 40% of all HIV infections; also commercial sex workers (CSW) are at high risk to be infected by HIV (and other sexually transmitted diseases) (Offergeld et al., 2014). Further data for Europe were published (ECDC/WHO, 2020) documenting an HIV infection in approximately 43% for MSM when people were diagnosed late (CD_4 cell count $<350/mm^2$). HIV infection of MSM is reported globally (e.g., Lama et al., 2010; Beyrer et al., 2012; Wang et al., 2012; Hakre et al., 2014; Jansen et al., 2015) and the infection with HIV increases the probability to be infected by further sexually transmissible viruses as HBV and HCV (Falade-Nwulia et al., 2015; Melhem et al., 2015; Das et al., 2018). It has to be considered that HIV, HCV and HBV (together with some new emerging viruses as Zika virus) is detected in human semen (Salam and Horby, 2017). MSM and bisexual men can transmit HIV (and other blood-borne viruses) to women and may subsequently cause the infection of children (e.g., Khanani et al., 2011). As mentioned above, besides HIV also HCV can be transmitted by sexual activity and MSM, being HIV infected, have a higher risk also to acquire an HCV infection (e.g., Witt et al., 2013) and an HBV infection (e.g., Tseng et al., 2012; Van der Kuyl et al., 2013). Transmission of HBV by sexual contacts are a known cause of HBV infection (e.g., Li et al., 2010; Soetens et al., 2015; Cornelissen et al., 2016; Inoue and Tanaka, 2016; Dah et al., 2019). Further viruses, as hepatitis A virus, were reported to be transmitted by sexual contacts (Sfetcu et al., 2011; Raczynska et al., 2019). Besides MSM, also female CSW are infected by blood-transmissible viruses (e.g., Rosenberg and Weiner, 1988; Weber et al., 2002; Wang et al., 2009; Offergeld et al., 2014). Therefore, the higher HIV prevalence and incidence among MSM, compared to the general heterosexual population, demand a thorough assessment whether MSM and concurrent sexual partners of bisexual men as well as CSW could be potential blood donors. This assessment should include changes from a permanent donor deferral policy for MSM to a risk-based deferral policy based on scientific evidence. Therefore, in several countries MSM (and, partly, CSW and their (multiple) partners) are not any longer permanently deferred but, depending on the last MSM

(or other sexual) contact, a deferral period of 12 or even 3 months were implemented according to the respective national regulatory authorities; this limited deferral period is set up after having assessed that the change in deferral policy results in no significant increase of risk (Suligoi et al., 2013; Epstein et al., 2014; Ginsberg et al., 2016; FDA, 2020d; Steele et al., 2021); due to NAT screening of donations with a high sensitivity and the detectability of a virus infection within, commonly, approx. not more than 6 weeks, after infection, such a limited deferral policy of 3 months seems appropriate from a scientific point of view.

Also the use of drugs, primarily injectable drugs, are a high risk to be infected with blood borne viruses, primarily HIV, already recognized in the late 1980s (e.g., Robertson et al., 1986; Webb et al., 1986; D'Aquila and Williams, 1987). Sexual contacts of illicit drug users, including CSW, can transmit pathogens to the general population (e.g., Brown and Primm, 1988; Ramsey et al., 2010; Thurstone et al., 2013). Further virus infections are reported for illicit drug users as HCV (e.g., Firestone Cruz et al., 2007; Aaron et al., 2008; Magalhães Novais et al., 2009; Basu et al., 2015) and HBV (e.g., Moestrup et al., 1986)—here, vaccination seems to decrease the probability of HBV infection (Rivas et al., 2010).

Based on these data the main risk for recipients originates from donors with sexual risk behavior such as MSM and sexual contacts with CSW, illicit drug users, and persons from countries with a high prevalence of HIV, HCV and/or HBV. Therefore, when no permanent deferral of potential donors is implemented by the national regulatory authority, an individual risk assessment covering the sexual risk has to be performed; the same is true for individuals having used in the past illicit drugs. Information about risk behavior of donors, first time donors and repeat/regular donors, has to be given to a donor prior to each donation by a donor's interview based on the questionnaire.

The questionnaire, discussed above to be used to protect the donor's health, is also relevant for the recipient's health. Therefore, the questions include, but are not limited to, any history of injectable drug abuse, sexual contacts of MSM and contacts with CSW, but also, e.g., female partners of men having sex with men, and sexual contact with residents or former residents of countries with a high prevalence of, e.g., HIV. Body piercing and/or tattoo and acupuncture treatment by a not registered practitioner may have an increased risk of infection with blood borne viruses when the hygiene in such establishments is low (e.g., Van Remoortel et al., 2019). Finally, the risk of having received a xenotransplantation has to be assessed in order to prevent a zoonotic disease that could be transmitted to the recipient of a blood component and, in principle, also by a PDMP (e.g., Fishman et al., 2012; Denner and Mueller, 2015). Furthermore, geographic risk regarding vCJD disease has to be answered as well as treatment in the past with extracts from pituitary glands or receiving dura mater or cornea grafts as well as having a family risk of Creutzfeldt-Jakob disease (EMA, 2018; FDA, 2016; revised recommendations by the FDA (FDA, 2020e) with clarification regarding less stringent requirements for deferral of donors).

Temporary deferral regulations are implemented when a donor has/had certain medical treatment/medication or diseases. A donor of source plasma is commonly not deferred due to infections with viruses, except for HIV, HCV, and HBV with a permanent deferral established. For some viruses as parvovirus B19 (B19V) and HAV (as well as HEV in certain regions or for specific PDMPs), the donor is deferred until a sensitive NAT assay is non-reactive in order to predict that a plasma pool for fractionation is below a predefined virus load that has to be demonstrated. Due to the fact that PDMPs are manufactured with a range of process steps to fractionate, purify, and concentrate the desired protein(s) that are finally sterile filtered, most human infectious viruses, when causing a non-persistent infection, as well as bacteria and parasites do not result in a deferral of a source plasma donor (e.g., EDQM, 2020; FDA, 2009a, 2017, 2019, 2020a; O'Brien et al., 2012). For donors of blood and blood components more stringent exclusion criteria apply.

Epidemiology in donor population

Testing each donation for the presence of the major blood-borne viruses HIV, HCV and HBV is of utmost importance to prevent an infection of recipients of PDMPs (compare topic Donation Screening). Such testing establishes a continuous epidemiological surveillance of the donor population in order to ensure long-term safety of plasma for fractionation (WHO, 2007). This surveillance provides information on the prevalence and incidence, and their trends, of infectious markers relevant to the virus safety of PDMPs as accurately as possible. In case predefined limits in the epidemiology are exceeded, appropriate measures (e.g., CAPA—corrective action and/or preventive action) have to be taken without delay to bring the respective donor population, e.g., at a specific blood/plasma collection center within a country or region, back to conformity. Detailed information on the assessment of epidemiological data on blood transmissible infections can be found in an EMA guideline (EMA, 2016a).

Assessing the data from epidemiological surveillance will detect differences among donor populations at various collection centers caused by differences in viral markers, potentially reflecting differences in donor selection and screening procedures; CAPA should be taken to address such an issue. Trends in infectious markers, reflecting either a change in the rate of viral markers in the population, a possible deviation in the donor selection or screening process at specific collection sites, and/or the implementation of a new or additional screening test has to be assessed carefully, and, if required, appropriate counter measures have to be executed. When in a particular blood establishment a significant higher prevalence or incidence rate is demonstrated, a comparison with the general population in the same country/region is useful in assessing the suitability of this blood establishment for collecting plasma for the production of PDMPs. It has to be considered, however, that prevalence and incidence are generally complementary in providing information on past and current risk of infection in a population: a high prevalence and incidence is characteristic for an ongoing transmission, high prevalence and low incidence demonstrate a high infection rate in the past with intervention measures introduced in the meantime, low prevalence and high incidence indicates an infection (most probably) introduced recently into the population, and a low prevalence and incidence is indicative for little or no evidence of past or current infection.

Theoretical Blood Establishment in a Country / Region

Fig. 5 Graphical tool for assessing the epidemiology in a donor population of theoretical blood/plasma establishments in a country/region. As an example, blood/plasma establishment X is considered an outlier with efficient CAPA. (A) Country/region with low prevalence and incidence: example for HIV in repeat tested donors. (B) Country/region with high prevalence and incidence: example for HCV in first time tested donors. (C) Country/region with high prevalence and incidence: example for HCV in repeat tested donors.

A graphical tool (e.g., control chart) is very suitable to compare the epidemiological situation in a given blood establishment with all collection facilities in the same country/region and the general population. Fig. 5 shows the principle of such a graphical tool demonstrating the comparability of the incidence and prevalence in the first time tested donor population with the general population. Positive screening results of repeat donors indicate primarily the incidence rate of an infection and the continuous donor education and interviews based on a questionnaire reduces the risk that a donor infected with a blood-borne virus will show up at a blood establishment or will be accepted as donor. In this theoretical situation shown in Fig. 5, only Blood Establishment X is in 1 year (year 2) outside the upper Confidence Interval (CI) for all establishments; implementing effective CAPA, the incidence (and partly prevalence) in the donor population of this establishment came back to specifications. The epidemiology in the general population is comparable to that in donors for Fig. 5B, whereas the epidemiology in repeat tested donors (Fig. 5C) is considerably lower than in the general population, even in a country/region with a high prevalence and incidence.

Further measures have to be in place to define an acceptable epidemiology in a donor population as outlined in detail in the European requirements to apply for Plasma Master File (PMF) certification submitted to EMA (EMA, 2016a; EMEA, 2006a,b). A major issue in assessing the donor population's epidemiological data is monitoring change over time and defining alert and action limits. Change over time should be provided separately for "repeat tested donors" and "first time tested donors," even if source plasma (collected by apheresis) from first time tested donors is not used to produce PDMPs; the screening data of these first time tested donors may relate to the epidemiology in the general population. When source plasma as well as recovered plasma

(from whole blood) is collected in a certain country/region for the production of PDMPs, it is recommended to monitor the donor populations separately as the interdonation interval in both populations is considerably different resulting in an improved determination of the incidence rate in source plasma donors.

The epidemiological surveillance provides information on differences among donor populations of various collection centers which may be associated with objective differences in viral markers within donor populations or may reflect differences in the process of donor selection and screening among collection centers; when such differences are due to donor selection or screening procedures, appropriate CAPA could diminish these differences. Furthermore, trends over time in the rate of viral markers have to be assessed in such a way that differences in epidemiology can be distinguished to be either due to a change in the epidemiology in the donor population, potential modifications in the donor selection process, or change in screening methods or processes at specific collection sites. The implementation of new or modified screening tests as a serological assay with improved sensitivity and, especially, the introduction of a NAT assay may impact the documented epidemiology in the donor population (compare topic "Screening of Donations"). Such modification of the screening procedure has to be carefully assessed when comparing the epidemiology over time.

Establishing an acceptable epidemiology in the donor population requires first to define the prevalence and incidence in a donor population (EMA, 2016a). Only confirmed infections (confirmed seropositive results) have to be considered; regarding NAT results, "NAT only positives," i.e., the donation is tested non-reactive in serological assays, have to be evaluated. For each blood establishment, information on the donor population including the frequency of donations (average number of donations from one donor per year) has to be compiled; information whether donations from "first time tested donors" are used in plasma pools (generally, only recovered plasma from first time tested donors is used for the production of PDMPs) has to be included. The definition for prevalence and incidence is as follows (EMA, 2016a):

- the prevalence is calculated as $[\text{number of positive "first time tested donors" in a specific period (commonly a calendar year)}] / ([\text{total number of "first time tested donors" in the same specific period}] * 100,000)$
 - "first time tested donors" are persons who are "tested for the first time for infectious disease markers (with or without donation) and without evidence of prior testing in a given blood system" (EMA, 2016a).
- the incidence (in repeat tested donors) is calculated as $[\text{number of positive repeat tested donors in the study period with a previous negative donation}] / ([\text{total number of donations from repeat tested donors in the study period} * \text{mean interdonation interval (expressed in years)}]) * 100,000$
 - a "repeat tested donor" is a "person whose blood/plasma has been tested previously for infectious disease markers in a given blood system," (this includes "regular donors" and "repeat donors"). For PMF holders using the applicant/qualified donor system, "repeat tested donors" include "applicant donors" tested for a second time, "applicant donors" requalifying after an interval of 6 months or more, and "qualified donors" (EMA, 2016a).

To cover also transient detectable amounts of HBV markers, an adjustment factor should be applied (EMA, 2016a); as a very conservative approach, the assumption by Korelitz et al. (Korelitz et al., 1997) may be used; i.e., 5% would have persistent antigenemia (or HBV DNA), 70% of infected donors would have transient antigenemia (or HBV DNA) lasting on average 77 days (Seed et al., 2002) and 25% of infected donors would have no antigenemia (or HBV DNA (thus, these 25% are not considered in the formula)). The following formula should be applied: $1 \div ((0.05 * 1) + (0.7 * (77 \div (\text{IDI}))))$. It has to be considered, however, that the IDI (interdonation interval—in days) is applicable when the IDI is more than 77 days, otherwise the probability to detect a transient antigenemia (or NAT detectability)—lasting on average for 77 days—is 1.¹

Furthermore, the residual risk that a donation from an infected donor remains undetected has to be estimated. The inability of a screening assay to detect an infection is due to (i) the detection limit of a screening assay: the current absence of antibodies (serological assay) or virus (NAT assay; very recent infection with no viremia) in blood/plasma (window period) or (ii) mismatch of virus markers/nucleic acid with assay components due to e.g., virus variants/mutations. This window period risk for serology testing could be estimated as the product of the incidence rate and the time interval in which a new infection would not be detected. Based on published data, considering also the improved sensitivity of assays over time, this window period is considerably different for HCV serology and NAT assays; for HIV and HBV the difference between sensitive serology assays and NAT are lower. Table 2 shows the detection of an infection based on serological assays with the corresponding virus load in a donation non-reactive in serology and the considerably improved detectability of a virus infection with low virus loads in a donation remaining non-detected by NAT testing.

The virus load in a donation in a NAT positive donation detected by NAT ("NAT only") considered here is based on a generic NAT assay with an average 95% Limit of Detection for HIV-1, HCV, and HBV of 50 IU/mL, 10 IU/mL, and 5 IU/mL, respectively. The virus doubling time, related to the NAT window period, is shown in Fig. 4.

Serological donation screening assays are on average reactive 22, 82, and 59 days after infection by HIV, HCV, and HBV, respectively (Table 1; Schreiber et al., 1996). Therefore, when using serological assays an inventory hold period of 60 days is generally only efficient for HIV as a donation tested non-reactive would be detected by subsequent donations of this donor within the time period of 60 days. For HCV as well as for HBV this inventory hold period is considered inappropriate when testing solely

¹Examples to calculate the HBV adjustment factor: Donor of recovered plasma donating twice a year (IDI of 180 days): $1 \div ((0.05 * 1) + (0.7 * (77 \div 180))) \geq 2.9$
Donor of source plasma donating once a week (as IDI of 7 days is below 77 days, the transient antigenemia (or HBV NAT) would be detected within these 77 days: $1 \div ((0.05 * 1) + (0.7 * (1))) \geq 1.3$).

Table 2 Window period for HIV, HCV, and HBV assays.

	<i>HIV-1</i>	<i>HCV</i>	<i>HBV</i>	<i>Reference</i>
Serological window period [days]	22	82	59	Schreiber et al. (1996)
Virus load in a serological window donation (up to [$\log_{10}$ IU/mL donation])	5.8 ^a	6.6 ^b	2.4 ^c	^a Ribeiro et al. (2010) ^b Glynn et al. (2005) ^c Biswas et al. (2003)
NAT window period [days]	15	8	35	EMA (2016a)
Estimated virus load after NAT testing (= non-reactive donation) [IU/mL ($\log_{10}$ IU/mL) donation]				Based on average 95% limit of detection for HIV-1, HCV, and HBV of 50 IU/mL, 10 IU/mL, and 5 IU/mL, respectively [approx. corresponding to package inserts of assay suppliers]
Single donation testing	50 (1.7)	10 (1.0)	5 (0.7)	
Minipools testing				
Pool of 24	1200 (3.1)	240 (2.4)	120 (2.1)	
Pool of 16	800 (2.9)	160 (2.2)	80 (1.9)	
Pool of 6	300 (2.5)	60 (1.8)	30 (1.5)	

serology. High virus loads, especially for HCV, would remain undetected and such a donation—tested negative in a serological assay—would be pooled for the production of PDMPs. Therefore, the implementation of NAT assays is essential to identify high titer donations and remove/discard these donations; an inventory hold period of 60 days is considered adequate when NAT testing is implemented, taking into account an interdonation interval of less than approximately 7 up to 14 days.

Criteria to establish alert limits for epidemiological data has to be defined and may, depending on the epidemiology in different countries/regions, be related to the epidemiology of the general population in the specific country/region. These alert limits allow the identification of individual collection centers of a blood/plasma establishments with viral marker/virus rates outside the normal range for the given donor population in this defined country/region triggering appropriate corrective actions. Due to the fact that the interdonation interval is considerably different between source and recovered plasma donors, the infection markers and/or viral load in a donation of an infected donor may be more often below the limit of detection of the respective screening assays in recovered plasma than source plasma; the epidemiology in the donor population should, therefore, be assessed for recovered and source plasma donors independently. The risk of accepting donations containing a low virus load (below the limit of detection of the NAT assay system used) for the production of PDMPs is, therefore, higher for recovered plasma, especially when the inventory hold period measure for source plasma is implemented.

Drawing a donation from an infected donor is related to the prevalence and incidence rate for a given virus in the donor population; when the donation is tested non-reactive in serological and NAT screening assays (window period donation), the incidence rate in the donor population is relevant. This incidence rate corresponds to the likelihood that recent infections are detected when the viral markers or virus load are above the limit of detection of the assays employed. Estimating the risk of a donation from an infected donor remaining undetected is primarily assessed for blood/blood component transfusion (e.g., Weusten et al., 2002; Niederhauser et al., 2005; Zou et al., 2010). Besides this general concept to assess the risk of undetected infected donations, for plasma for fractionation such a risk and, thus, acceptable epidemiological rates in the donor population, is currently assessed by two approaches:

- Defining a “Standard” of the epidemiology in a donor population to compare current epidemiology and possible outliers is performed by compiling historical epidemiological data of one or several blood/plasma establishments over one or several years. Statistical methods are applied, e.g., gamma distribution of the epidemiology in donor populations (as the distribution of center specific positivity rates is highly asymmetric, usually with a high peak at the lower end, near zero, and a long right tail), together with the Poisson distribution for the number of positive donors in a given center; such an approach is implemented for PPTA blood/plasma establishments and donation centers (PPTA, 2010).
- An appropriate margin of virus safety in the finished PDMP (according to the European Guideline on PDMPs EMA, 2011) is used as starting point to back-calculate the maximum virus load in the plasma pool for fractionation, considering the virus reduction capacity for HIV, HCV, and HBV for a theoretical PDMP; the number of donations below the limit of detection of the NAT assay (tested in minipools) correlates with the incidence rate in the donor population and, based on these estimates, an alert but also an action limit for a defined collection center was calculated. Alert limits could be defined triggering closer monitoring of the collection center whereas action limits trigger predefined CAPA (Lovick et al., 2014) when the incidence rate was higher. This concept employs a probabilistic Monte Carlo model, comparable to approaches published (Janssen et al., 2008; Velthove et al., 2013); however, in these publications an acceptable epidemiology for PDMPs was not outlined.

Screening of donations

Tests to detect a virus infection of a donor in a sample of a donation have to be applied as the probability of virus transmission by blood components and, in the past, by PDMPs, depends on the frequency of infections in the donor population, the duration of the

asymptomatic phase of an infected donor, and the length of the viremia. Such a test has to be specific and sensitive; e.g., cross-reactivity between antibodies against viruses of the same family or genus should be excluded (e.g., [Souza et al., 2019](#)). After the detection of the respective virus in the general populations or in individuals at risk to acquire a virus infection, in-house assays, developed commonly first by research institutes, followed by commercial assays, are employed to detect the virus infection.

Serological assays detect virus specific antibodies and virus antigens commonly using enzyme immunoassays as enzyme-linked immunosorbent assay (ELIA) or chemiluminescence assay (ChLIA). Only licensed or approved (CE-mark) assays, according on the relevant regulatory agencies, can be used for screening of donations. A positive result of a serological assay has to be confirmed, employing, according to the nationally established algorithm, an alternative immunoassay, a Western blot or recombinant immunoblot; tests using a different detection principle as antigen detection (when testing for antibodies was performed) or NAT may be suitable in the interpretation of uncertain screening test results. Initially reactive donations should be tested for confirmation in duplicate and if any of the repeat tests are reactive, the donation is considered repeat reactive and a confirmatory assay has to be used.

Besides the detection of virus proteins (antigens) and antibodies against certain virus proteins, the detection of the virus nucleic acid by nucleic acid amplification techniques (NAT) is widely implemented as this screening assay is the most sensitive assay to detect a virus infection early. These NAT assays are commonly PCR (polymerase chain reaction) assays requiring repeated temperature changes (thermal cycles) and, when an RNA virus has to be detected, the transcription of virus RNA to DNA. Besides PCR, mainly a TMA (transcription-mediated amplification) assay, an isothermal process, is employed in testing donations; for this assay, DNA from DNA viruses has to be transcribed into RNA to start the reaction. Internal controls are added to the reaction mixture in commercial NAT assays and the amplification efficacy is followed by fluorescent or chemiluminescent signals. Modifications of the general methods are available as (droplet) digital PCR for precise quantification of nucleic acids; furthermore, for the detection of a very wide range of viruses (and other pathogens), including new emerging viruses, Next Generation Sequencing (NGS) methods are applied meanwhile. Besides qualitative also quantitative NAT assays are available defining, besides the Limit of Detection, also the Limit of Quantification. Further developments of (commercial) NAT assays result in multiplex assay formats allowing the detection of different viruses (primarily HIV, HCV and HBV) simultaneously in a single sample of a donation.

- HIV
 - First assays to detect anti-HIV antibodies were described in the mid 1980s and questions regarding the implementation of such assays were discussed in a Consensus Conference ([Consensus Conference, 1986](#)). Currently, the fourth generation serological assay is implemented in many countries, detecting simultaneously anti-HIV antibodies and HIV antigen. The minimum requirement for a HIV serological screening test is the detection of anti-HIV-1 M, including outlier types as HIV-1 type O (and type N as well as some HIV-1 circulating recombinant forms (CRF)) and anti-HIV-2.
 - HIV NAT assays should be able to detect all relevant HIV-1 groups/subtypes and HIV-2 including mutations and circulating recombinant forms (CRF) of HIV. As HIV is genetically very variable, NAT assays have to target very conserved genome sequences as primers. Nevertheless, there are reports that such an approach may not be sufficient and that the simultaneous use of at least two conserved regions as amplification target ("dual target screening") should be used ([Schmidt et al., 2009](#); [Chudy et al., 2012, 2014](#)).
- HCV
 - The agent causing the parenterally transmitted "non-A, non-B hepatitis" (now known as hepatitis C virus (HCV)) was first described 1989 ([Choo et al., 1989](#)); based on a cDNA clone, the detection of antibodies in the majority of non-A, non-B serum specimens was possible ([Kuo et al., 1989](#)) resulting in the first serological detection of anti-HCV antibodies. Currently, a third-generation antibody assay is available (and a fourth-generation assay detecting antibodies as well as antigens). NAT assays for the detection of HCV are very important as the long window period in serology screening can be closed considerably and the high virus load in a window period donation can be detected and the donation destroyed (and the donor deferred permanently).
- HBV
 - Serological assays detect the HBV surface antigen (HBsAg); the envelope of HBV is composed of host-derived lipid components and three virus-encoded polypeptides, collectively called HBsAg (the S gene with three in-frame start codons and a common stop codon dividing the gene into PreS1, PreS2 and S region encoding the small, middle and large envelope proteins, respectively). HBsAg can be detected in serum/plasma not only as part of the whole virus but also as separate spherical or tubular sub-virus particles; these sub-virus particles do not contain DNA and are non-infectious and exceed the amount of intact, infectious HBV particles in serum/plasma up to 10,000-fold; however, for different HBV genotypes, especially genotype G, the release of HBsAg particles in blood is considerably lower, resulting in a decreased detectability of certain HBV genotypes ([Hassemer et al., 2017](#)). Due to the fact that mutations in the S gene as well as so-called occult HBV may not be detectable by HBsAg screening assays (e.g., [Consensus Report, 2004](#); [Ly et al., 2006](#); [Scheiblaue et al., 2006](#)), antibodies against the HBV core protein (anti-HBc), lasting for a long time after infection, are implemented in some countries for blood/blood components for transfusion (e.g., [Schmidt et al., 2006](#)). It has to be considered, however, that in the early phase of an HBV infection antibodies against HBc have not been developed.

Due to the generally high sensitivity of the HBsAg assay, the detection of very recent infections by HBV is not considerably shorter by the implementation of an HBV NAT.

A full validation of commercial test kits used in the testing facility is not required when a thorough description of the methodology and reagents according to the manufacturer's instructions is followed. However, a verification that the operators at the testing facility, when using appropriate equipment, material, and reagents in the testing facility's environment and applying the manufacturer's instructions, achieve the same outcomes as defined in the validation data provided by the kit manufacturer is essential. A statistically significant number of samples covering the full range of results for the intended use should be exerted. The verification should confirm that the limit of detection (LOD) or limit of quantitation (LOQ) are comparable to the validation data of the kit manufacturer. The testing facility should also participate in collaborative studies organized by an independent organization to demonstrate reproducibility between laboratories.

In order to compare results of screening assays between different testing facilities, defining the analytical sensitivity of different testing methods and the performance of laboratories, is of utmost importance. Therefore, WHO International Standards (IS) are implemented to meet regulatory requirements as minimal NAT sensitivity. ISs are measurement standards assigning an internationally agreed unitage in International Units (IU). The potency of an IS is determined through international collaborative studies using a range of methods typically in routine use by participating laboratories (Baylis et al., 2015, 2019). In the first collaborative study for HCV NAT standardization, a very wide range of methods (different in-house and commercial assays) were employed demonstrating a difference in sensitivity of at least 4 log₁₀ (Saldanha and Minor, 1996a). With improved experience of the participants in performing NAT assays, the difference between laboratories (blood product manufacturers, kit producers, regulatory organizations as well as reference laboratories) decreased in international collaborative studies (e.g., Saldanha et al., 2001). Comparability of results by different NAT methods and testing laboratories measured in IU, especially at low level concentrations of virus nucleic acid, is essential to release donations and, especially in Europe, release of plasma pools for further processing. International Standards are not only available for NAT assays but also for serological assays, e.g., for HBsAg (Seiz et al., 2016).

Besides IS, reference panels or international reference panels are available (e.g., from NIBSC, <https://www.nibsc.org/linkhandler.ashx?pid=4624>) and consist of different genotypes or relevant strains of viruses from different global regions (Baylis et al., 2019); no unitage is assigned to members of international reference panels. These international reference panels, when studied in routine testing approaches, document the detection of variants or, on the other hand, demonstrate a gap in the detectability of a range of virus variants. Thus, improvements of assay performance may be triggered when the detection of specific variants is suboptimal. WHO had published available International Reference Preparations (WHO, 2018).

Testing donations has to be performed according to the relevant regulatory requirements applicable in the respective country where the donation is collected; besides serological testing, NAT testing is required (e.g., FDA, 2004, 2012). For source plasma donations fractionated and the PDMP marketed in another country, regulations of this third country may also apply. Testing is performed at least for the major blood-borne viruses human immunodeficiency virus (HIV), hepatitis C virus (HCV), and hepatitis B virus (HBV) by serological assays (antibodies against HIV-1/-2 and HCV as well as HBV surface antigen (HBsAg)) and in most countries also by nucleic acid amplification assays (NAT) as PCR or TMA for HIV-1/-2, HCV, HBV and commonly also for parvovirus B19 (B19V) (e.g., FDA, 2009b) and, voluntarily, for hepatitis A virus (HAV); only donations non-reactive in all assays performed will be further processed to PDMPs. Donors being infected with HIV-1/2, HCV or HBV will be permanently deferred from donation. As all tests have a limit of detection, and especially antibody assays detect an infection after the respective virus replicated to high titers, the presence of infectious virus in a donation cannot be excluded despite having performed an antibody test for each single donation accurately, as shown in Fig. 6.

Donations reactive in serological assays have to be retested and, if repeat reactive, confirmation of the test result has to be performed using a different test method.

A "NAT only" result should also be confirmed at least by repeat testing. When NAT testing is performed in a minipools setting, the destruction of the minipool and identification of the reactive donation is acknowledged as a repeat reactive result. It has to be considered, however, that for qualitative assays the Limit of Detection is based on the Probit analysis of a dilution series (compare Fig. 7) and a very low virus load, detected with a low probability, may not result in a repeat reactive donation. When testing minipools and the minipool is deconstructed to identify the reactive donation, the probability to detect the reactive single donation is higher; the dilution factor by pooling is vanished and the virus concentration in a sample of the reactive donation is higher by the factor of the minipool size (nevertheless, an, e.g., six fold higher virus concentration compared to the load in a minipool of 6 may not always result in a repeat reactive donation; statistical evaluations may define the number of "repeat studies" that, with a high probability, a low virus load would be detected again).

Besides HIV, HBV and HCV, further viruses—not causing a persistent infection—are included in a routine screening approach when the plasma pool for fractionation has to be below a certain virus load. This is the case for parvovirus B19 (B19V) as the plasma pool for fractionation should not exceed 4 log₁₀ according to FDA regulations (FDA, 2009b). Studies performed previously document that, without B19V NAT testing, plasma pools as well as PDMPs may contain a high amount of B19V DNA sequences (Schmidt et al., 2001) and solvent/detergent treated pooled plasma transmitted B19V caused illness (Koenigbauer et al., 2000). In contrast to common PDMPs only solvent/detergent treatment is applied during the production of this product and this treatment has no effect on the non-enveloped B19V. Therefore, risk mitigation strategies had to be implemented as thorough B19V screening of donations and limiting the amount of B19V in the plasma pool.

Implementation of hepatitis A virus (HAV) NAT was introduced by many manufacturers of PDMPs on a voluntary basis as reports were published documenting a low, but not zero, risk of HAV transmission by PDMPs (e.g., Chudy et al., 1999, 2002). In addition, another hepatitis causing virus, hepatitis E virus (HEV), is recognized to have a blood-borne phase: HEV is a major cause of acute clinical hepatitis among humans throughout the world. In developing countries acute hepatitis E in humans is caused

Fig. 6 Schematic principle of antibody and NAT screening assays. Implementation of NAT screening assays reduces the Diagnostic Window period by antibody screening and minimizes the virus load in a donation released due to non-reactivity in the serological assay.

Fig. 7 Probability to detect a virus infected donation based on probit analysis. S-shaped cumulative normal distribution with very low virus concentration to be detected with low probability and increased probability to detect higher virus concentrations.

by the HEV genotype 1 (HEV-1; occurrence mainly in Asia) and genotype 2 (HEV-2; occurrence mainly in Africa and Mexico) with a host range restricted to humans. These genotypes are transmitted primarily by the fecal/oral route (primarily by contaminated water) (Kamar et al., 2012). In industrialized countries, HEV genotypes 3 and 4 are zoonotic viruses infecting animals such as swine, wild boar and deer; transmission to humans occurs primarily by consumption of undercooked pork and wild boar products or by contact with infected animals (Colson et al., 2010; Pavio et al., 2017). HEV (genotype 3) seems to be present more often in donations from European donors than in US donors as data from donation screening indicate (Baylis et al., 2012b; Roth et al., 2017).

As HEV transmission by transfusion of blood/blood components was reported (e.g., Andonov et al., 2014; Domanovic et al., 2017; Gallian et al., 2019), screening of blood donors for the presence of HEV RNA was implemented in some countries; interestingly, elevated ALT (alanine transaminase) levels are not indicative of an HEV infection (Baylis et al., 2010). The presence of HEV in plasma pools for fractionation was also reported with a HEV RNA load not exceeding 1000 copies/mL HEV RNA even without HEV NAT screening of donations (Baylis et al., 2012a). Despite the fact that HEV genotype 3 is considered a threat for immune compromised people (e.g., transplant recipients) and patients with underlying liver impairment or disease, the European regulatory agency does not recommend a general HEV RNA screening of donations and release of plasma pools for fractionation for further processing as the HEV load is low and currently licensed PDMPs contain at least one manufacturing step effective against non-enveloped viruses. No HEV transmission cases have been reported so far with the currently produced plasma-derived medicinal products, with the exception of pooled solvent/detergent-treated plasma (EMA, 2016b; Andonov et al., 2014; Gallian et al., 2020). Therefore, the European Pharmacopoeia requests that the plasma pool for the production of pooled solvent/detergent treated plasma has a limited HEV load of not exceeding 320 IU/mL HEV IU/mL (Ph. Eur. 01/2020:1646); this requirement can only be achieved by screening donations for HEV genomic material and interdicting reactive donations.

Release of plasma pools for fractionation

The plasma pool for fractionation is considered to represent the starting material of PDMPs by regulatory agencies in some countries, comparable to the unprocessed bulk of cell culture derived biotechnological products (ICH, 1999). According to the Ph. Eur. Monograph "Human Plasma for Fractionation" (Ph. Eur. 0853), as an example for comparable regulations worldwide, only donations from carefully selected, healthy donors after medical examination and acceptable donor's medical history, as well as blood screening tests for blood-transmissible viruses could be used for the production of PDMPs. In certain regions of the world, e.g., Europe, the first homogenous pool of plasma (generally after removal of cryoprecipitate) has to be tested for anti-HIV-1/-2 and anti-HCV antibodies and HBsAg using test methods of suitable sensitivity and specificity; the pool has to be negative in these tests in order to manufacture PDMPs; furthermore, the plasma pool has to be tested also for HCV RNA and has to be non-reactive (European Pharmacopoeia monograph "Human Plasma for Fractionation (0853)") using a validated NAT assay. A positive control with 100 IU/mL of hepatitis C virus RNA and, to test for inhibitors, an internal control prepared by addition of a suitable marker to a sample of the plasma pool are included in the test. The test is invalid if the positive control is non-reactive or if the result obtained with the internal control indicates the presence of inhibitors. The plasma pool complies with the test if it is found non-reactive for hepatitis C virus RNA and detects the run control (positive control) of 100 IU/mL HCV RNA. This NAT test was introduced in Europe in 1999, when intramuscular immunoglobulins, which did not have a validated, effective inactivation/removal step for (enveloped) viruses, transmitted HCV despite thorough anti-HCV antibody screening of all donations (CPMP, 2001); the addendum to this guideline was deleted in the fourth revision (EMA, 2011) as HCV NAT testing of plasma pools became a mandatory requirement in the European Pharmacopoeia monograph "Human Plasma for Fractionation (0853)." When performing a qualitative HCV NAT assay to release a plasma pool (<100 IU/mL), the 95% Limit of Detection (LoD) of this HCV NAT assay, performed commonly by the fractionator or on behalf of the fractionator, should be around 30 IU/mL or lower as the 100% LoD is approximately three fold higher than the 95% LoD based on Probit Analysis in order to detect always the run control (100 IU HCV RNA/mL).

Further NAT tests have to be implemented when a plasma pool for fractionation is used for the production of "Human Plasma (pooled and treated for virus inactivation)," so-called SD-Plasma. As the manufacturing process is virtually only effective in the reduction of enveloped viruses, the amount of non-enveloped viruses in the starting material plasma pool has to be limited (Ph. Eur. 01/2020:1646): For hepatitis A virus, a plasma pool can only be released when the pool sample is non-reactive, a positive control of 100 IU/mL HAV RNA is detected and the internal control is not affected by inhibitors; for HEV, a positive control of 320 IU/mL HEV RNA has to be detected and not more than 10.0 IU/ μ L of B19V DNA (10 IU/ μ L corresponds to 10,000 (4.0 log₁₀) IU/mL) would be detected. The general requirement for release of plasma pools for fractionation with a B19V load not exceeding 10⁴ IU/mL (FDA, 2009b) is applied by most manufacturers of PDMPs; therefore, the Ph. Eur. requirement for human anti-D immunoglobulin with a maximum 10.0 IU/ μ L B19V DNA is met virtually worldwide.

The release of plasma pools with a minimum HCV load as required in Europe is achieved by screening of all donations by a sensitive NAT assay. This is documented already in 1996 for most of plasma pools: 95 plasma pools from 6 manufacturers of PDMPs were tested and only 5 pools resulted in HCV RNA positivity; all these reactive plasma pools were fractionated by one manufacturer (Saldanha and Minor, 1996b). After PPTA (Plasma Protein Therapeutics Association) member companies had implemented voluntarily testing of (source plasma) donations for HIV-1 (later-on also HIV-2), HCV and HBV, PPTA implemented a NAT standard as part of its voluntary standards (PPTA, 2013). The effect of this NAT screening approach was documented in a further study assessing the impact of NAT screening on the potential contamination rate of plasma pools: 873 plasma pools created in 1996 (prior to the European agency's recommendation to implement HCV NAT testing from July 1, 1999 onwards; CPMP, 2001) were tested and 17.8% were HCV RNA positive, 0.8% were HIV-1 RNA positive and 0.5% were HBV DNA positive. The virus load in the positive pools were up to 3*10⁴ IU HCV RNA/mL, up to 6.4*10³ IU HIV-1/mL and the HBV load was below the limit of quantification (54 IU HBV DNA/mL). From 331 plasma pools created in 2006 none were HIV-1 RNA and HBV DNA positive and only in one pool a very low load of HCV RNA (<10 IU HCV RNA/mL) was detected (Nübling et al., 2008). NAT testing of donations and release of plasma pools for fractionation based on non-reactivity of the plasma pool provides confidence that donation testing was performed correctly, and no mix-up of donations occurred.

Table 3 Assumed virus load in plasma pool for fractionation of 2000 L based on epidemiology.

	Recovered plasma			Source plasma		
	7150			2500		
	HIV	HCV	HBV	HIV	HCV	HBV
Prevalence/incidence in donor population (per 100,000)	2.7 ^a	12.8 ^a	24.2 ^a	0.05 ^b	0.18 ^b	0.05 ^b
Number of donations per pool from donors assumed to be infected	0.2	0.9	1.7	0.06	0.22	0.06
Calculated virus load per pool [mL], based on minipool (16) NAT limit of detection ^c	0.11	0.02	0.01	0.36	0.07	0.05

^aIncluding 15% first time tested (FTT) donors in plasma pool (prevalence/incidence rate per 100,000 for FTT donors: 7.9 (HIV), 69.5 (HCV), 134.5 (HBV)).

^bAssuming 85% efficacy of inventory hold, the relevant epidemiology regarding pool contamination rate is 0.3 (HIV), 1.2 (HCV), 0.3 (HBV).

^cConsidering at least one donation from an infected donor below the limit of detection of the respective NAT assay in each pool.

Considering the virus load in a theoretical plasma pool for fractionation, the following parameters are assumed as an example provided in Table 3:

- the epidemiological situation in Germany for the blood-transmissible viruses HIV-1, HCV, and HBV (Offergeld et al., 2010) with prevalence/incidence rates (per 100,000 donors) of first time tested (FTT) donors for recovered plasma of 7.9, 69.5, and 134.2 for HIV-1, HCV and HBV, respectively and for repeat tested (RT) donors of 1.5, 2.4, and 4.1 for HIV-1, HCV and HBV, respectively, as well as for source plasma (RT donors) of 2.1, 7.7, and 2.1 for HIV-1, HCV and HBV, respectively
- a plasma pool prepared from recovered plasma contains 15% plasma from FTT donors; one donation per donor enters a plasma pool
- a plasma pool prepared from source plasma contains 15% of donations stored in Inventory Hold released after 60 days Inventory Hold without a subsequent donation tested assuming as worst case that these donations are just below the limit of detection of the NAT assay; two donations per donor enter a plasma pool
- NAT screening is performed in a minipool testing scheme of 16 donations/minipool and a limit of detection of 50 IU/mL, 10 IU/mL and 5 IU/mL for HIV-1, HCV and HBV, respectively. The contamination of a plasma pool could be expected considering a virus load per mL donation of ≤ 800 IU/mL, ≤ 160 IU/mL, ≤ 80 IU/mL for HIV-1, HCV and HBV, respectively, with 95% probability (compare Table 1)
- size of the theoretical plasma pool for fractionation is 2000 L; the volume of a recovered plasma donation is 280 mL and of a source plasma donation is 800 mL

Table 3 shows that a low virus load in plasma pools for fractionation may be present according to the assumption discussed above; it has to be considered, however, that a worst-case assumption is applied that each and every plasma pool contains at least one donation from an infected donor, which was non-reactive in NAT screening assays (as only a whole donation and not a fraction can be pooled). Single donation, instead of minipool, screening will reduce the virus load further but the number of donations per plasma pool from an infected donor remains the same as the epidemiology remains the same. The probability that such a low virus load will be detected by NAT release assays for plasma pools is remote.

The higher prevalence/incidence rate in recovered plasma donor's epidemiology results in a significant higher number of donations from donors of recovered plasma being infected in a plasma pool for fractionation. The virus load in a pool is, however, comparable for both donor types according to the calculation used in Table 3 as the volume of a recovered plasma donation is substantially smaller than that of a source plasma donation. As in the calculation of the virus load per plasma pool always one donation having entered the plasma pool is considered, but only a fraction of a donation is present in a plasma pool based on the calculation, it can be assumed that in reality a considerably larger number of plasma pools prepared from source plasma contain no donation from an infected donor than a plasma pool prepared from recovered plasma.

It can be concluded from Table 3 that markedly increased epidemiological rates may result in a NAT positive plasma pool for fractionation. Measures as thorough donor selection criteria, highly sensitive NAT assays and, especially, Inventory Hold approaches for source plasma, have to be applied under these conditions. Furthermore, the implementation of Alert/Action Limits to collect plasma only from collection centers with viral marker rates within an acceptable epidemiology in the donor population is essential.

Conclusion

Source plasma or (in most countries) also recovered plasma are combined to large plasma pools for fractionation of commonly several thousand donations for the production of PDMPs. As in a donation, even after testing, a virus contamination may be present, due to the detection limit of screening assays, the plasma pool for fractionation may contain a substantial load of blood-borne viruses despite appropriate testing of donations, in particular when using only antibody testing. Especially for pharmacovigilance purpose, each donation (and, thus, donor) has to be traced to a finished product batch and backwards to support e.g., assessments of adverse drug reactions.

In order to mitigate the virus contamination of a plasma pool for fractionation, a wide range of measures are in place at the collection centers (blood establishments) and by the fractionator/manufacturer of PMDPs

- At the blood establishment (blood/plasma collection facility)
 - a Quality System based on GMP with quality standards appropriate to their intended use covering, e.g., personnel and organization, documentation system, premises and equipment, materials, qualification and validation, storage and transport, record keeping, documentation and review of results, change control, CAPA, complaints, recalls and audits as well as contract between blood establishment and fractionator. Blood/plasma has to be approved for release for further processing by specifications defined, validated, and documented. When an Inventory Hold or Quarantine process is in place, the release of donations for further processing relies on thorough forward and backwards traceability of all donations in order to interdict a donation with a virus load below the limit of detection, tested non-reactive, by a positive screening result from a subsequent donation. This will allow to destroy window period donations to a high degree. Alert and action limits for epidemiological data have to be established.
- Selection of donors
 - the health of donors has to be checked by a medical examination and by answers to a predefined questionnaire; the interdonation interval, according to national regulatory guidance, has to be followed.
 - the risk of transmitting a blood-borne disease, primarily caused by viruses, has to be explained to the donor by appropriate educational material. Answering a pre-defined questionnaire elicits information relevant for the recipient's health as any history of injectable drug abuse, risky sexual behavior and body piercing and/or tattoo and acupuncture treatment by a not registered practitioner. Finally, geographic risk regarding vCJD disease has to be answered as well as treatment in the past with extracts from pituitary glands or receiving dura mater or cornea grafts as well as having a family risk of Creutzfeldt-Jakob disease.
- Screening of donations
 - each and every donation has to be screened by serological assays for HIV-1/-2, HCV, and HBV; in order to close the window period with high virus loads for HIV and, especially HCV, NAT assays are used. These NAT assays detect a low virus concentration in a donation resulting in the destruction of such a positive donation, and previous donations from that donor stored in Inventory Hold. In order to meet the requirements by national authorities and voluntary standards by most manufacturers of PDMPs, further NAT tests are implemented; besides HAV NAT screening, to support the overall margin of HAV safety for a given PDMP, B19V NAT screening of donations is implemented (that the plasma pool not exceeds 10^4 B19V DNA/mL) also to achieve a sufficient margin of safety for this virus, which is resistant to physicochemical treatment, and, finally, donations to manufacture pooled solvent/detergent treated plasma have to be screened also by HEV NAT.
- Release of plasma pools for fractionation
 - in many countries the first homogenous plasma pool, the starting material of PDMPs, is released based on non-reactivity in serological assays for HIV-1/-2, HCV, and HBV. In addition, NAT testing and release of plasma pools for fractionation is a requirement for HCV in Europe (based on Ph. Eur. monograph) and for B19V based on a FDA guideline, and, for selected products as anti-D immunoglobulin, also in a range of other countries besides United States. According to the Ph. Eur. Monograph for pooled solvent/detergent treated plasma, further-on B19V, HAV and HEV NAT of plasma pools has to be implemented not exceeding specifications. On a voluntary basis, most fractionators are releasing all plasma pools for further processing only when also non-reactive in NAT testing besides serology testing.

These measures, when applied rigorously, assure a minute amount of relevant blood borne viruses in the starting material for plasma-derived products and, together with the manufacturing process of these products with build-in effective virus inactivation and/or removal steps, a finished drug product derived from human plasma is manufactured with a high margin of virus safety.

Introduction

According to the World Health Organization, infectious diseases have been emerging at an alarming rate (WHO, 2015). Since the 1970s, there have been nearly 40 infectious diseases reported, which includes viral pathogens such as the coronaviruses causing Severe Acute Respiratory Syndrome (SARS; including the novel Coronavirus Disease-19 virus), Ebola, Chikungunya, and Influenza A viruses of zoonotic potential (Menon et al., 2020). The increased rate of international travel, rising population, and frequent exposure of humans to wildlife has enhanced the risk of transmission of infectious agents (Hansen and El Wahed, 2020; Menon et al., 2020). The current strategies for the control and management of infectious diseases involves: (1) control of the infection source; (2) cutting off transmission routes; and (3) protection of susceptible people. Of these, controlling the source of infection is the key factor which can be attained by implementing approaches that facilitate early detection, isolation, and treatment of patients. For implementing such strategies, it is vital to develop rapid, sensitive, and accurate pathogen detection methods (Wang et al., 2021).

Over the years, advances in diagnostics has led to the development of laboratory-based tests for pathogen identification such as enzyme-linked immunosorbent assays (ELISA), polymerase chain reaction (PCR) tests and other confirmatory microbiological procedures. Previously, diagnostic clinical microbiology generally involved time-consuming procedures for identifying viral or bacterial pathogens. Such laboratory protocols require prolonged turnaround time (up to 14–21 days) and a higher demand for technical, spatial, and economic resources (Samuel, 2020). With the emergence of novel infectious pathogens burdening the global health epidemiology, it is crucial to have diagnostic tools that provide a quick turnaround of results for identifying pathogens in resource-constrained settings (Fonkwo, 2008; Drain et al., 2014; Zarei, 2018). Moreover, the novel laboratory based diagnostic technologies are out of reach of the majority of the world's population since they are complex, centralized, and require skilled operating personnel. Considering the limitations of classical laboratory tests, affordable and user-friendly commodities developed from the point-of-care perspective are critical tools for diagnosis of medically relevant and zoonotic pathogens (Menon et al., 2020). Point-of-care testing (POCT) platforms provide real-time and accurate diagnosis of patient's health at the site of care and enables clinicians to provide treatment options in a prudent manner (Chen et al., 2016; Kozel and Burnham-Marusich, 2017). This chapter highlights the history, current trends and advancements of point-of-care testing platforms adapted for use in diagnosis of invasive pathogens affecting humans.

History, current trends, and characteristics of POC testing devices

During the early years of the 20th century, Dochez and Avery developed an immunoassay for the detection of pneumococcal polysaccharide from serum and urine samples of patients suffering from lobar pneumonia. In this period, the authors speculated that such antigen detection will aid in the rapid diagnosis of infection (Dochez and Avery, 1917). The advent and actual application of point-of-care testing began in 1962 which led to the development of a rapid testing platform for blood glucose measurement utilizing an enzyme membrane electrode design (Clark and Lyons, 1962). By the last quarter of the 20th century, the US Congress passed the Clinical Laboratory Improvement Amendments (CLIA) act in 1988. In this regulatory framework, point-of-care testing has been available in hospitals although the diagnostic tests have never been performed outside the laboratory (Lewandrowski et al., 2011). This regulation was enacted in response to concerns for quality of laboratory testing and involved guidelines related to POCT, which were overseen at the Federal Government level by the Center for Medicare Services (CMS) (Fraunberger et al., 2018). However, the US Food and Drug Administration (FDA) issues the guidelines on how to interpret the CLIA regulations for categorizing POCT devices as “waived” and “non-waived” based on their complexity (Samuel, 2020). POCT devices that are cleared by the FDA for home use (outside of the hospital) are waived from the CLIA regulations. In general, the “waived” tests are used for outpatient practices and are considered simple and accurate methods whose probability of inaccuracy in results will not harm the patient in any way. However, POCT platforms used in healthcare systems are categorized as non-waived tests and regularly inspected for compliance in personnel qualification, training/competency, quality control systems, patient test result management, proficiency testing and validation. Regulatory compliance of CLIA non-waived tests is overseen by accreditation agencies such as the College of American Pathologists (CAP) and the Joint Commission (JC) (Fraunberger et al., 2018; Samuel, 2020).

POCT in diagnostic microbiology

Early stages of POCT development for clinical microbiology involved the use of rapid microscopy or immunochromatography (card, dipstick or lateral flow assays) (Bissonnette and Bergeron, 2010). However, the recent trends indicate that advancements have been made in POCT device which employ principles of isothermal nucleic acid amplification, and detection systems involving lateral flow, microfluidics, and plasmonic based systems (Nath et al., 2020; Zhao et al., 2020; Sharafeldin and Davis, 2021). Some of the important characteristics of POCT is that: (a) the tests can be performed right next to the patient; (b) the tests can be outside a laboratory setting; (c) there is minimal need for sample preparation (d) it requires special measuring devices that utilize ready to use reagents for a single sample measurement; (e) it does not require technically qualified medical personnel for operating the device; (f) the results will be available quickly and help to provide a rapid diagnosis for follow-up treatment (Luppa et al., 2018). Considering the characteristics of diagnostic POCT, it has a greater applicability in resource-limited settings with limited infrastructure, information systems and human resources (Drain et al., 2014). In order to deploy diagnostic resources in resource-limited settings, the World Health Organization (WHO) has proposed a series of standards called the “ASSURED” criteria (Affordable, Sensitive, Specific, User-friendly, Rapid, Equipment-free, Delivered to those in need) (Bissonnette and Bergeron, 2015). Although several advancements have been made in the development of scalable user-friendly diagnostics, most of these platforms have challenges associated with large-scale manufacturing, data management, regulatory approval and managing test errors generated by the end user. With the issues of potential zoonotic pandemics threatening human wellbeing, global efforts have concerted to the refinement of such technologies as a tool for improved epidemiological control, food safety and general biodefense (Sharafeldin and Davis, 2021). Additionally, the reduced turnaround time for such diagnostics will positively impact the patient and the community, healthcare workers, as well as the socioeconomic aspects of healthcare (Bissonnette and Bergeron, 2015). The recent advancements in POCT has led to the development of novel technologies and the miniaturization of existing technologies with improved assay performance (Samuel, 2020).

Analytes tested in POCT platforms for diagnostic microbiology purposes

Currently available POCT platforms can detect the following analytes for pathogen identification (Kozel and Burnham-Marusich, 2017; Samuel, 2020):

- (a) Antigens: antigenic components of the pathogen are identified using a specific antibody. The antigen-antibody complex thus generated is further detected by a platform that utilizes lateral flow assay or its modified variant. Some of the examples include rapid testing kits for influenza A or group A streptococcal antigen testing.
- (b) Antibodies: Such tests will involve the detection of antibodies directly from blood or serum samples toward specific pathogens, for example, human immunodeficiency virus (HIV).
- (c) Nucleic acid detection: These tests will involve the direct detection of pathogen related genomic DNA or RNA from the patient sample. Most of these tests employ nucleic acid amplification tests such as polymerase chain reaction.
- (d) Host derived proteins as biomarkers: These proteins help to distinguish classes of infecting microbes, i.e., to distinguish bacterial from viral infections. In acute infections, the biomarkers involved may be related to serum acute phase proteins, cytokines or host-specific nucleic acid signatures that differentiate from bacterial and viral infections.

In the following sections, we have discussed major POCT diagnostic platforms that have been utilized for the diagnosis of infectious diseases in humans.

Lateral flow assay based diagnostic systems

For nearly four decades, lateral flow devices have been used for applications such as pregnancy self-testing, foodborne pathogen detection, disease diagnosis, biomarker screening and environmental monitoring (Leuvering et al., 1980; Stragier and Losick, 1996; Džunková et al., 2016; Huang et al., 2020; Jarvis et al., 2020; Lan et al., 2020; Yin et al., 2020; Wang et al., 2021). Infectious disease diagnosis using lateral flow devices has been popular as a point of care diagnostic tool due to their simplicity, ease of operation, rapid turnaround of test results, cost effectiveness with minimal user intervention (Wang et al., 2021). Lateral flow assays follow the principle of an immunochromatographic system which relies on the binding of a microbial antigen in clinical samples to conjugated primary antibodies (with nanoparticles or fluorescent labels). This bound complex is recognized and captured downstream by secondary antibodies leading the appearance of a colored band. The flow through of the unbound and excess primary antibodies moves further downstream to be captured by a tertiary antibody. The banding pattern produced by the tertiary antibody capture typically acts as an interpretable test result or the control line (Drancourt et al., 2016). The basic components of a lateral flow based diagnostic system involve a nitrocellulose membrane, sample pad, conjugate pad, membrane, test line, control line and absorbent pad found in tandem as a test strip (Fig. 1). Each component of the test strip will be pre-impregnated with the respective chemicals and reagents (antibodies and visible signal-generating system) for visual appraisal of the expected confirmatory reaction. Sample fluid gets loaded into and adsorbed into the sample pad. The analytes seep from the sample pad to interact with analyte-specific labeled molecule in the conjugate pad to form antigen-antibody complexes (primary complex). Further on, the conjugated analyte moves and interacts with the immobilized capture molecules (anti-antibodies or the secondary antibody) in the nitrocellulose membrane because of the capillary force provided by the absorbent pad toward the end of the test strip. The unbound primary antibody moves forward to interact with the tertiary antibody to produce a color reaction at the control line. Analytes with the immobilized capture molecules occurs as a result of non-covalent interactions (e.g., electrostatic interaction, hydrophobic interaction and hydrogen bonding) and aid in the production of a signal at the test line that can be detected by the naked eye without the need for specialized equipment (Gubala et al., 2012; Reali et al., 2019; Li et al., 2020). This technology has been adapted for the detection of pathogens such as Ebola virus, Yellow fever virus, Herpes simplex virus, Rotavirus, Adenovirus, *Clostridioides difficile*, *Campylobacter* spp., *Streptococcus pneumoniae*, *Legionella pneumophila*, and *Neisseria gonorrhoeae* (Drancourt et al., 2016).

Apart from the benefits of low cost, quick turnaround of results and the lack for need of instrumentation or a power source, lateral flow assay (LFA) systems have low sensitivity (~60–95%) and the results of test interpretation is operator dependent, which

can lead to false-positive or false-negative results (Drancourt et al., 2016). However, novel and advanced immunochromatographic based lateral flow assays have been developed for molecular diagnosis (Realí et al., 2019). During the past decade, there has been significant and promising advancements made in improving the portability, accuracy, and sensitivity utilizing microfluidics and plasmonic based technologies (Chen et al., 2019). More information related to these technologies have been explained in the upcoming sections of this chapter.

Molecular based diagnostic systems

Traditionally, laboratory bench top-based diagnostics for nucleic acid based pathogen identification is accomplished using quantitative polymerase chain reaction (PCR). This procedure requires the need for trained laboratory personnel, costly equipment and consumables. However, over the past two decades, isothermal based nucleic acid amplification has developed as an alternative tool for conventional qPCRs which can be easily performed at a single and constant temperature without the need for a thermocycler (Pumford et al., 2020). In this section, we will be explaining the loop-mediated isothermal amplification and recombinase polymerase amplification which is currently developed for pathogen detection.

Loop-mediated isothermal amplification

Nearly two decades ago, Notomi and coworkers discovered a novel method termed as Loop-mediated Isothermal Amplification (LAMP) that amplified DNA with high specificity, efficiency and rapidity under isothermal conditions (Notomi et al., 2000). The operative simplicity and rapid turnaround for test results pave way for the development of point of care technologies based on the principle of LAMP (Pumford et al., 2020). An amplification rate of 10^9 – 10^{10} -fold of the target DNA sequence occurs at a temperature range of 60–65 °C in 15–60 min (Itou et al., 2014; Chen et al., 2016). The length of the amplicons generated through LAMP ranges from approximately 300 bp to 10 kb whereas the conventional PCR produces target DNA copies of uniform size. A LAMP reaction mixture consists of *Bst* DNA polymerase, deoxynucleoside triphosphates (dNTPs), double-stranded target DNA, and four primers specific to each target sequence. LAMP reaction typically involves a self-primed DNA amplification favored by the strand displacing activity of the *Bst* DNA polymerase (derived from *Bacillus stearothermophilus*). The four primers comprise of two outer and two inner primers. The inner primers are designed in such a way that DNA amplicons generated from them are capable of forming a loop structure. Primers are designed in such a way that it amplifies target sequences that are typically less than 300 bp and sequences above 500 bp are poorly amplified due to the rate-limiting step of the strand displacement DNA synthesis. A LAMP reaction is initiated by one of the inner primers (forward inner primer or FIP, and backward inner primer or BIP). The FIP hybridizes to the target sequence and get extended by the strand displacement activity of the *Bst* polymerase to replace one of the original DNA strands of the double helix (Fig. 2-I). Subsequently, the forward outer primer (F3) hybridizes upstream of the FIP amplified DNA and initiates the displacement and release of the strand containing the FIP. By virtue of the complementary sequence present in the released strand, it favors the formation of the loop structure. A similar process occurs on the opposite end of the target DNA sequence with the backward inner primer and the backward outer primer (BIP and B3). As a result, a target amplicon with self-hybridizing loops on either end is formed resulting in a dumbbell shaped structure which has multiple sites for initiation of the second cyclic stage of the LAMP reaction (Fig. 2-II). Eventually, multiple copies of these dumbbell structures are elongated and amplified exponentially in the third stage of LAMP giving rise to duplex stem-loop DNAs of various lengths, with each single strand containing inverted repeats of the target sequence (Fig. 2-III) (Notomi et al., 2000).

Some of the detection methods employed for identifying LAMP derived products involve colorimetric indicator-based, turbidity-based, and fluorescent-dye based applications. Colorimetric indicators such as hydroxynaphthol blue (HNB) which change the color of the reaction from violet to sky blue as and when the magnesium ions get utilized for the amplification process (Goto et al., 2009). Turbidity-based detection works on the principle of identifying magnesium pyrophosphate, a white salt precipitate derived as a by-product of the LAMP reaction (Tomita et al., 2008). Fluorescent dye capable of intercalating with LAMP products such as SYBR Green 1, EvaGreen, SYTO 81, Calcein and fluorescently labeled oligonucleotide strand displacement probes have been employed for detecting various viral pathogens. Recently, Lamb and coworkers developed a SYBR Green 1 fluorescence-based RT-LAMP assay was developed for detection of SARS-CoV-2 from human samples such as serum, urine, saliva and swabs collected from oro-nasopharyngeal sites (Lamb et al., 2020).

Recombinase polymerase amplification

In 2006, Pipenburg and coworkers developed the recombinase polymerase amplification (RPA) technique which employs recombinant proteins to amplify DNA (Piepenburg et al., 2006). Typically, in an RPA reaction (see Fig. 3), the loading factor protein called T4 UvsY enables the formation of the recombinase-primer complex by promoting T4 UvsX recombinase binding to the oligonucleotide primers. Such complexes screen double stranded DNA for homologous sequences and favor strand dissociation at the target recognition site. Stabilization of the unfolded DNA containing the recombinase-primer complex is achieved with the help of single-stranded DNA binding proteins. The resultant binding of the recombinase-primer complex to the target leads to the dissociation of recombinase and concomitant binding of the strand displacing activity of the large fragment of *Bacillus subtilis* POL I DNA polymerase (devoid of exonuclease activity) to the 3' end of the primer favoring the elongation and cyclic amplification of the target site.

Fig. 2 Pictorial representation for the mechanistic basis for LAMP. (I) Initiation of LAMP results in the generation of a dumbbell structure. (II) Stem-loop structures are generated in the cyclic stage of LAMP. (III) Stem loop structures are elongated; amplification occurs exponentially. From Notomi T, et al. (2000) Loop-mediated isothermal amplification of DNA. *Nucleic Acids Research* 28: 63. CC BY 4.0 license: <https://creativecommons.org/licenses/by/4.0/>.

Lateral flow assay (LFA) based detection of RPA amplicons was subsequently developed in tandem by Piepenburg and coworkers (Piepenburg et al., 2006). In this system, an additional carboxyfluorescein bearing probe and two internal primer pairs specific for the RPA amplicons (one of the primers is a 5' biotinylated primer) is required apart from the two RPA primers. The details of the RPA-LFA system is provided in the figure below (Fig. 4). The fluorescent probe is 42–56 nucleotide long that contains a 5' carboxyfluorescein label (5'FAM), an internal abasic site (tetrahydrofuran), and a 3' block. With the help of recombinase proteins, the probe is exchanged at the target recognition site that harbors the 5' biotinylated tag on the opposing end. Subsequently, cleavage of the abasic site by the double strand specific *E. coli* endonuclease IV (Nfo) and removal of the 3' block (extension blocker) of the probe. The probe is converted to a primer and DNA polymerase (purple) begins extension. As a result, 5'FAM and biotin-labeled amplicons are generated which is then read out in the LFA system at the detection line having α -biotin antibody as shown below.

Fig. 3 Pictorial representation for the mechanistic basis for RPA. The reaction is initiated by the binding of the T4 UvsX recombinase (yellow) to the primers with the help of the T4 UvsY loading factor (orange). The recombinase-primer complexes scan dsDNA for homologous sequences, and they invade these sequences with the strand-displacement activity of the recombinase. Single stranded binding proteins (purple) stabilize the displaced strand and the recombinase dissociates, leaving a 3' group available for extension. Strand displacing DNA polymerase (green) binds the 3' end of the primers and extension begins, eventually resulting in two DNA duplexes. Reprinted with permission from Pumford EA, et al. (2020) Developments in integrating nucleic acid isothermal amplification and detection systems for point-of-care diagnostics. *Biosensors and Bioelectronics* 170: 112674., Copyright 2020, Elsevier B.V.

The readers are advised to refer to the publication by Pipenburg and coworkers for obtaining more detailed information related to the RPA based LFA system. The technology is currently commercialized by TwistDx™ in the form of the Milenia HybriDetect 1 and the Milenia HybriDetect 2 and several researchers have utilized this technology for detection of bacterial, rickettsial and protozoal pathogens which is capable of acquiring results with 1 h with a limit of detection as low as 10 DNA copies per reaction (Chao et al., 2015; Nair et al., 2015; Saldarriaga et al., 2016; Lalremruata et al., 2020; Pumford et al., 2020).

CRISPR-Cas based detection systems

Since 2017, CRISPR technology has been applied in molecular based diagnosis with increased sensitivity for detecting zeptomolar (10^{-21} M) concentrations of nucleic acid targets with single nucleotide resolution (van Dongen et al., 2020; Wang and Cui, 2020). In addition, CRISPR-Cas system has been applied as a point-of-care testing platform for detecting nucleic acid targets derived from isothermal nucleic acid amplification reactions such as LAMP or RPA (van Dongen et al., 2020). The CRISPR-Cas effectors are generally classified in two classes: Class 1 and Class 2. CRISPR/Cas class 1 system is composed of a complex of multiple effector proteins that performs a single function, whereas the class 2 systems are characterized by one single effector protein harboring multiple functions with the CRISPR process (Makarova et al., 2020). Some of the class 2 systems include Cas9, Cas12, Cas13 and Cas14. The principle behind the application of CRISPR/Cas as a biosensing tool is based on the collateral cleavage of untargeted

Fig. 4 RPA-LFA based read out system as a point of care platform. (A) Schematic for the generation of 5'-FAM and biotinylated labeled amplicons and the lateral flow strip detection system. (B) Schematic of the lateral-flow probe design (top, here Lfs1) and its arrangement relative to amplification primers (bottom, here orfX and sccII). FAM label (green), biotin label (red). (C) Lateral-flow strips used for the detection of RPA products (products amplified are specific for three polymorphic alleles of the methicillin resistant *Staphylococcus aureus* [MRSA] *mec* gene; the orfX is shared by all three alleles whereas primers specific for MRSAI/II and MRSAIII target the *mec* variants). Reactions contained (left to right) 10 copies of MRSAIII, 10 copies of MRSAII, 10 copies of MRSAI, or 10,000 copies of MSSA (methicillin sensitive *S. aureus*; negative control) as template. Positive signals are generated in the first three reactions (filled arrowhead). The MSSA control reaction only produced a flow-control signal. From Piepenburg O, et al. (2006) DNA detection using recombination proteins. *PLoS Biology* 4: 1115–1121. CC BY 4.0 license: <https://creativecommons.org/licenses/by/4.0/>.

single stranded RNA or by the specific cleavage or binding of DNA as evinced by class 2 effector proteins. When effector proteins are associated with a CRISPR RNA (crRNA), this complex will detect and cleave complementary target sequences. In addition to this activity, this complex will also favor the cleavage of collateral untargeted single stranded RNA in its vicinity. This property is achieved by multiple Cas family members such as Cas13, Cas12 and Cas14 effectors. Whereas Cas9 effectors are involved in specific cleavage and binding of DNA. Some of the CRISPR-Cas effectors employed for pathogen diagnosis have been outline below.

Cas9 based systems

The RNA guided Cas9 systems can cleave double stranded DNA and this phenomenon has been applied in the detection and genotyping of American and African strains of Zika virus with single-base resolution by Pardee and coworkers (Pardee et al., 2016). The output of the reaction is detected using a toehold switch sensor that can generate a paper-based colorimetric reaction. With regards to the Cas9 based DNA binding without cleavage, it occurs by virtue of the application of nuclease-dead Cas9 (dCas9) system. In this DNA detection system, Zhang and coworkers produced a pair of dCas9 effector proteins linked to split halves of

luciferase protein will only be capable of luciferase heterodimerization when each effector-fusion protein detects two specific regions of the target DNA sequence of *Mycobacterium tuberculosis*. Upon detection of the respective regions of the target DNA by two dCas9-split luciferase effectors will enable the production of a bioluminescent signal without target DNA cleavage (Zhang et al., 2017).

Cas13 based systems

Formerly known as C2c2, this CRISPR-Cas effector system is a single-component enzyme capable of targeting single-stranded RNA molecules with the help of a guide RNA. Upon binding to the target ssRNA will promote its bifunctional nucleic acid cleavage properties that is directed toward cleaving the target RNA as well as collateral ssRNA molecules (Abudayyeh et al., 2016; East-Seletsky et al., 2016). In the SHERLOCK (specific high-sensitivity enzymatic reporter unlocking) platform, binding, and cleavage of the target RNA by Cas13 effector concomitantly facilitates the cleavage of the collateral reporter-quencher ssRNA molecules in reaction mixture thereby enabling fluorescence emission. This collateral fluorescence signal will correspond to the cleavage of the target RNA in the sample. This methodology has been applied for the detection of nucleic acid sequences derived from isothermal amplification processes (e.g., RPA) to detect Dengue virus and Zika virus from patient samples (Myhrvold et al., 2018).

Cas12 and Cas14 based systems

Cas12a or Cpf1 effector proteins harbor a thymine (T) rich PAM (protospacer-adjacent motif) for target cleavage and an RuvC endonuclease domain. This system employs two detection platforms known as DETECTR (DNA endonuclease target CRISPR trans-reporter) and HOLMES (a one-Hour Low-cost Multipurpose highly Efficient System) to target DNA sequences in attomolar levels with high specificity (Wang et al., 2020), and has been used for the diagnosis of DNA and RNA viruses. The target nucleic acid sequence is initially amplified using RPA which is then subjected to binding with Cas12a-sgRNA complex to trigger cleavage of fluorescent-quencher based dsDNA target leading to the generation of a fluorescence signal (Chen et al., 2018; Li et al., 2018). Cas14 (subgroups "a" through "c") effector proteins are capable of targeted ssDNA cleavage without requiring a protospacer-adjacent motif for activation. Additionally, they also possess the domain responsible for non-specific ssDNA cleavage that is similar to the RuvC endonuclease observed in Cas12a effectors. Cas14a-DETECTR platforms have the potential to be used for viral pathogen diagnosis (Wang et al., 2020).

With most of the CRISPR-Cas based technologies having evolved during the span of 4 years, most of its applications are still in its developmental phases. One advantage of this platform is that it can be reconfigured and adapted to detect various pathogen and hence has the potential to be developed as a flexible diagnostic platform for identification of several infectious diseases. Also, utilization of genetically modified Cas effector with robust properties will pave way for the replacement of currently available isothermal based nucleic acid amplification systems (van Dongen et al., 2020).

Microfluidics-based systems

Microfluidics is a technology that processes small amounts of liquid (10^{-9} L or less) for chemical analysis, and diagnostics (Whitesides, 2006). Microfluidics employs microchannels or more extensive Lab-on-a-chip (LOC) for sample processing. Lab-on-a-chip refers to the integration of several laboratory capabilities on a microfluidic chip to facilitate easy, accurate and expedited sample processing (Arora et al., 2010). Microfluidics can also be combined with other detection technologies such as PCR, LAMP or mass spectroscopy for after-chip analyte detection. Some of the features of microfluidics that make the technology well suited for lab-on-a-chip, point-of-care applications are (1) ability to process small sample volumes (2) faster processing time via high throughput parallel analyses (3) low cost and (4) portability (Solanki et al., 2020). Microfluidic devices have been gradually developing over the past 40 years. However, the last 15 years has seen major advancements, especially in point-of-care diagnostic applications (Sachdeva et al., 2021).

Developing a microfluidics system requires several components including test samples, reagents, substrates, and appropriate micro-channel design. The preparation of sample is critical for successful use of microfluidics-based technology. For single components such as DNA, RNA or proteins, an isolation, purification, or concentration step might be needed before the sample could be loaded on the channels (Wu et al., 2014). PCR in combination with pre-enrichment is routinely employed to enrich sample concentration for microfluidics testing (Zhang et al., 2013; Tachibana et al., 2015). For multi-component or complex samples (e.g., soil, blood, tissue) where either multiple analytes or multiple organisms are present, a more extensive purification process is required (Wang et al., 2011). The selection of structure material plays an important role in determining the functionality and application of microfluidics device. Depending on the application, appropriate materials such as silicon, plastics, paper, hydrogels, glass or silicon are selected. These selected materials provide different properties, chemical compatibility, and conductivity to the system (Pandey et al., 2018). A brief description of select microfluidics systems along with their applications is provided below.

Silicon-based microfluidics devices

The use of silicon facilitates flexibility in the structure of the device and tolerance to varying external environmental conditions (Schöning and Lüth, 2001). The methods used for the fabrication of silicon-based microfluidics devices include bulk micromachining, surface micromachining, or buried channel (De Boer et al., 2000; Iliescu et al., 2012). In case of bulk micromachining, channels are created on silicon wafer by cutting of the material followed by enclosing in a secondary wafer and eventually bonding via chemical or physical adherence (Iliescu et al., 2012). Surface micromachining can be accomplished by a relatively complex process involving deposition of a structural layer followed by etching of a secondary layer. Buried channel system is created by starting with a deep reactive ion etching, followed by a passivation step via chemical vapor deposition or SiO₂ (De Boer et al., 2000). Some of the commonly tested analytes include cytokines, peptides, interleukins, and antibodies (Jenison et al., 2001). The aforementioned analytes have been used to detect human cystic fibrosis (Jenison et al., 2001) and *Escherichia coli* in human blood sample (Yakovleva et al., 2002; Das et al., 2012).

Glass-based microfluidics devices

Glass is a non-crystalline solid that is extensively used in microfluidics systems primarily due to its chemical inertness, transparency, and surface stability. The development of a microfluidics device with a glass platform employs MEMS processes including photolithography, film metallization, and glass etching (Pandey et al., 2018). Numerous applications of glass microfluidics have been reported for detection of antibody, enzyme or cell proteins (Grego et al., 2012; Mirasoli et al., 2013), coliform bacteria (Sahdan et al., 2017) and foodborne pathogens (Zhao et al., 2019).

Paper-based microfluidics devices

Paper-based devices use paper or other porous, hydrophilic membranes for microfluidics applications. Unlike traditional microfluidics devices made of silicon or glass, paper-based devices are more economical, easily disposable and can perform multiplexed assays with similar efficacy (Nishat et al., 2021). In addition, paper-based devices can be readily stored, stacked or transported without significant loss in performance of the assay. They employ capillary action for liquid movement in the microchannels and therefore do not normally require pumps to operate fluid movement. Paper-based microfluidics instruments meet the ASSURED (Affordable, Sensitive, Specific, User friendly, Rapid and Robust, Equipment free, Deliverable to end-user) criteria established by the World Health Organization (Hu et al., 2014; Cate et al., 2015). Two of the most commonly used paper-based devices include dipstick assays and lateral flow assays (e.g., home pregnancy test). Most recently, the lateral flow test has been developed for the detection of COVID-19 (Broughton et al., 2020; Choi, 2020).

Several previous studies have investigated the potential of microfluidics for early pathogen detection. Stokes et al. (2001) developed a Cy5 labeled antibody based microfluidic system for detecting *E. coli*. The biochip featured a 4 cm square array of independent operating photodiodes along with amplifiers, and logic circuitry on a single platform with 0.4 mL of reaction chamber. The microfluidics chip was able to detect ~20 *E. coli* strains in simple as well as complex medium (e.g., milk diluent) (Stokes et al., 2001). In another study, Keays et al. (2016) designed a microfluidics platform for characterization of antibiotic resistance patterns in *E. coli*. The susceptible and resistant strains were cultured in microfluidics channels called droplet culture and characterized for various biochemical and resistance parameters (Keays et al., 2016). Similarly, a microfluidics system was developed to detect *Salmonella* using anti-*Salmonella* polyclonal antibodies with a sensitivity of 3 log CFU/mL of sample (Møller-Kristensen et al., 2007). A smartphone-based device has been used in combination with paper-based microfluidics assay for rapid detection of *Salmonella* Typhimurium (Park et al., 2013), and *E. coli* (Dieckhaus et al., 2021). The technique involved pre-coating the microfluidics surface with anti-*Salmonella* or anti-*E. coli* antibody followed by addition of sample, and immunoagglutination of sample-antibody complex. The immunoagglutination was quantified using Mie scatter intensity via a smartphone followed by evaluation on a standard curve. The detection limit was single cell level with a total assay time of less than 1 min. Lee et al. (2009) designed a microfluidic chip for detection of *Mycobacterium tuberculosis* using the *rpoB* gene-based amplification (Lee et al., 2009). Similar microfluidic systems or mChip designs have been developed to detect *Salmonella* in poultry package (Fronczek et al., 2013), *Neisseria gonorrhoeae* (Cho et al., 2015) Hepatitis B (Wang et al., 2012a), HIV (Wang et al., 2012b), HBV (Zhang et al., 2010), or Zika virus (Song et al., 2016).

One of the major challenges faced by point-of-care microfluidics is the difficulty in detecting low concentrations of analytes in sample volume. While there are several techniques to concentrate analytes at larger volume (e.g., liquid-liquid extraction, solid phase extraction, microwave-assisted extraction), concentrating smaller volumes is still in the initial stages of development. Some of the techniques currently being investigated for analyte concentration for microfluidics applications include (1) stacking methods such as amplified sample stacking, isotachopheresis, (2) gradient focusing such as isoelectric focusing, temperature focusing, electric field focusing and (3) trapping mechanisms including electrokinetic trapping, immunocapture, magnetic beads assisted trapping and thermophoretic trapping (Zhao et al., 2017).

Plasmonic technology-based systems

Optical biosensor devices are emerging as powerful platforms for point-of-care detection and disease diagnosis. Optical biosensor devices that are based on refractive index monitoring cover a range of technologies including plasmonics based platforms. Plasmonics is a new branch of optics that derives its foundations in nanotechnology, quantum mechanics, subwavelength optics, and solid-state physics (Tokel et al., 2014). Plasmonics refers to the production, detection, and modification of signals at optical frequencies in the nanometer scale. Optical biosensors, especially those based on plasmonics, have developed in recent times for rapid disease diagnostics at point-of care (Fan et al., 2008). Here we have reviewed latest advancements in surface plasma resonance (SPR), localized surface plasmon resonance (LSPR) and surface enhanced Raman scattering (SERS) including target analytes and major challenges in their development.

Surface plasma resonance (SPR)

Surface plasma resonance is a label-free technique for real-time observation of various bio-molecular interactions between analytes and test compounds. Some of the routinely observed interactions include protein-protein (Kim et al., 2006), protein-DNA (Majka and Speck, 2006), protein-polysaccharide (Beccati et al., 2005), protein-virus (Zhang et al., 2014), enzyme-substrate (Fong et al., 2002). In preparation for detecting various analytes in a sample solution, capturing reagents such as antibodies, enzymes, peptides, or DNA are immobilized on the sensor metal surface of SPR chip. When the solution containing sample (target molecule) is introduced onto the surface, the aforementioned interactions occur that change the refractive index in the space around the surface which is detected by observing a change in the surface plasmon polariton wave. In SPR experiments, resonance units (RU) are used to describe the change in signal, where 1 RU corresponds to a critical angle shift of 10^{-4} degree (Nguyen et al., 2015).

SPR is increasingly being used for drug discovery, pathogen detection and metabolic disease diagnosis at point-of-care (Cooper, 2003; Homola, 2003). SPR based detection has been employed for detecting markers for infectious diseases such as human influenza (Misono and Kumar, 2005), HIV-1 (Tombelli et al., 2005), respiratory viruses (Shi et al., 2015), and metabolic diseases including diabetes (Su et al., 2008), Alzheimer's (Yang et al., 2014), neurodegenerative diseases (Wittenberg et al., 2014), and breast cancer (Jiang et al., 2005). P53 is a tumor suppressor gene which mediates cell cycle arrest and apoptosis. A mutation in p53 gene leads to oncogenic activities and drug resistance. SPR chip coated with p53 monoclonal antibody was used to identify mutant p53 proteins for rapid cancer diagnosis (Wang et al., 2009). In addition, SPR sensor based on oligonucleotide probes and nucleic acid hybridization are also being developed for detecting nucleic acid and genetic diseases (D'Agata and Spoto, 2013; Šípová and Homola, 2013).

Localized surface plasmon resonance (LSPR)

Similar in concept to SPR, the localized surface plasmon resonance is an optical phenomenon produced as a result of interaction between light and a surface, in this case, nanoparticles that are smaller than the incident wavelength (Hammond et al., 2014). This interaction produces unique characteristics including a plasmon propagation distance of $\sim 2\text{--}20\ \mu\text{m}$. While SPR can propagate an electromagnetic wave along a metal dielectric surface, the LSPR creates an amplified electric field for shorter distance. The short plasmon propagation distance provides the term "localized" to the terminology. The resonant frequency of the localized plasmon oscillation heavily depend on the composition, size, dielectric environment and separation distance of nanoparticles (Petryayeva and Krull, 2011). The technology has been used for real-time and point-of-care detection of enzymes, antigens, antibodies, and proteins (Liu et al., 2019). Majority of analytes have dimensions in the range of $2\text{--}20\ \text{nm}$ which is similar to receptor nanoparticles thus making them structurally compatible. This dimensional compatibility of nanoparticle-biomolecules complex facilitates the design of LSPR biosensors and their various applications (Sagle et al., 2011; Hammond et al., 2014). LSPR has been successfully used to identify DNA hybridization (Endo et al., 2005; Kim et al., 2007), Alzheimer's disease amyloid ligands (Stuart et al., 2005), and antigen-antibody interactions to diagnose diabetes (Hiep et al., 2008), or detect toxin peptides in samples (Ha et al., 2008). In addition, LSPR has been employed to detect influenza (Park et al., 2012), Zika (Takemura et al., 2019) and other infectious pathogens (Zopf et al., 2019; Bonyár, 2020).

Surface-enhanced Raman scattering (SERS)

Like SPR and LSPR, surface-enhanced Raman scattering spectroscopy (SERS) provides a non-invasive, label-free, and sensitive detection of a wide range of analytes for point-of-care diagnostics. SERS has its foundation in LSPR and like LSPR, uses molecular vibrations and amplifications of electric fields around a metal surface to facilitate single molecule detection (Granger et al., 2016). Since its discovery in the 1970s, SERS has been employed in various analytical and biological applications (Rohr et al., 1989; Stuart et al., 2005; Graham and Goodacre, 2008). Early work to develop SERS based analytical tools were thwarted by lack of nanomaterial that would support generation of consistent signal (Bell and Sirimuthu, 2006). With nanotechnology advancements that include nanostructure stabilization, polymer coating of surface, and development in spectroscopic instrumentation, researchers have been able to design nanoparticles with size, structure and material that is suitable for SERS applications (Burda et al., 2005). Due to the extensive research in this area, readers are referred to recent reviews (Sharma et al., 2013; Granger et al., 2016), which provide a

much broader and comprehensive discussion of SERS as a powerful diagnostic toolbox. Here, we have focused on key findings in the area of point-of-care diagnostics or rapid analysis of samples. Isola and coworkers designed a plasmonics-based silver nanoparticle assay for detection of HIV gag gene sequence. The assay employed stem-loop DNA tagged with a rhodamine derivate to act as a Raman-active reporter molecule (RRM) or a switch. In the absence of a target DNA, the stem-loop configuration kept the RRM close to silver nanoparticle surface thereby generating a strong SERS response. In the presence of the target molecule, RRM position is shifted, and the SERS signal was not generated (Isola et al., 1998). SERS has also been used to identify respiratory syncytial virus (Dluhy et al., 2008), urinary tract infection bacteria (Premasiri et al., 2017; Tien et al., 2018) and foodborne pathogens such as *Salmonella* (Draz and Lu, 2016; Ma et al., 2018; Xu et al., 2018). SERS has also been successfully used to detect ricin in liquid food. He and coworkers developed a two-step method in which Ricin B chain was captured out of food matrix by aptamer-conjugated silver dendrites and then the spectrum was read on the dendrites to detect small amounts of the toxin in food sample (He et al., 2011). Overall, plasmonic-based systems are becoming increasingly popular and effective in point-of-care diagnostics and various other applications in the biomedical and food industry.

Conclusion and future perspectives

Given the significant role of point-of-care diagnostics in the diagnosis of infectious diseases, it is critical to develop more cost-effective and easy-to-use detection platforms that can be operated by a lay person in resource limited settings. With most of the novel POCT platforms for infectious diseases being cost effective and being in early stages of research and development, transitioning to commercialization of these platforms would greatly benefit the medical diagnostic procedures and reduce the infrastructure related costs for the establishment of diagnostic laboratories. Additionally, future research and advancements should focus on the integration of these novel detection platforms as multiplexed based diagnostic system integrated and powered by artificial intelligence systems that can potentially act as early warning systems to stem potential uprisal of epidemics in a community or rather a possible global pandemic.

Introduction

The year 2020 marked awarding the Nobel Prize in Physiology or Medicine for the discovery of hepatitis C virus (HCV). More than 30 years before, in 1989, Michael Houghton and others published the first HCV genome sequence (Choo et al., 1989; Houghton, 2009). This discovery of HCV was enabled by preceding developments and culminated work of more than a decade since the first description in 1978, by Harvey Alter, of non-A non-B hepatitis as an agent transmissible by blood (Alter et al., 1978). However, after the 1989 first identification of a HCV sequence, it took another 7 years, until 1996, for the viral genome to be fully characterized (Kolykhalov et al., 1997). The many years required from clinical description to full genome characterization of HCV, by the end of the 20th century, stand in stark contrast to the full genome characterization of SARS coronavirus-2 (SARS-CoV-2), the virus responsible for coronavirus infectious disease 2019 (COVID-19), within a few weeks after the novel infection was recognized (Zhou et al., 2020; Zhu et al., 2020). Such a rapid discovery is a result of multiple technological developments, reviewed in this article. Moreover, immediate global sharing of the SARS-CoV-2 full genome sequence enabled the development of diagnostic tests and was essential for the fastest ever development and licensing of vaccines.

Emerging infections can be defined as either new infections, newly diagnosed infections, or infections that have increased in their geographic distribution, or which are increasingly found in vulnerable population groups, such as individuals with immunosuppression or intravenous drug users (Morens et al., 2004; Morse, 1995). Moreover, a combination of epidemiological evidence with microbiological identification has often resulted in the discovery of novel disease associations of known infectious agents

Table 1 Factors contributing to the emergence or re-emergence of pathogens.

<i>Factor</i>	<i>Emerging and re-emerging pathogens</i>
Incursion into natural habitats	Exposure to bat-borne paramyxoviruses such as Nipah virus, phyloviruses such as Ebolavirus and Marburg virus
Global travel	Rapid dissemination of 2009 H1N1 Pandemic (H1N1pdm09 virus); SARS-CoV-2 global pandemic
Host immunosuppression: HIV, organ transplant, immune suppressive therapies for cancer or connective tissue diseases	Opportunistic infections
Climate change	Vector borne disease (e.g., arboviruses)
Live oral polio vaccination to achieve herd immunity	Vaccine-derived polioviruses
Vaccine hesitancy	Measles outbreaks
Exotic animal trade	West African rodents: Monkeypox virus

(Morens et al., 2004). The last 30 years saw the discovery of many new or emerging infectious diseases, or infections that re-emerged or increased in incidence after periods of lower occurrence. The discovery and monitoring of novel and emerging pathogens have been made possible by many new developments in diagnostics, of which some of the most significant will be reviewed in this article.

Several factors are contributing to the emergence and re-emergence of pathogens (Table 1). Population growth has increased human incursions into regions where they are at increased risk of zoonotic infections. Climate change has increased the distribution of arthropod vectors and risk of human exposure to these pathogens. Global travel and trade networks have also resulted in an increasingly connected world population with the rapid dissemination of pathogens once they become established in humans. Changes in population vulnerability also contribute. HIV has resulted in the emergence of multiple opportunistic infections, which have recently declined with wider availability of antiretroviral combination therapy. Aging populations in industrialized countries may be increasingly vulnerable to particular pathogens due to immune senescence. Immune suppressive therapy is used in the context of organ transplantation, chemotherapy for cancer, or treatment for connective tissue diseases. These factors provide vulnerable populations to common and opportunistic pathogens (Morens et al., 2004). In addition, socio-economic development, secular trends, and vaccination behavior may either result in overall changes in the risk of infections or in the age of acquisition of particular infections, which influence whether individuals present with symptomatic or asymptomatic infection (Jacobsen and Koopman, 2005). Changes in the age of infection influence whether infections would occur in women of child-bearing-potential and resultant congenital infection, in case of rubella (Panagiotopoulos et al., 1999). Whereas vaccine campaigns have reduced the burden of many infectious diseases, it may have contributed to lesser awareness of the risks of vaccine preventable disease. Paradoxically the success of vaccination may have become the reason why people are less aware of real risks of acquiring infections and more aware of possible risks of vaccination and susceptible to antivaccine propaganda. This has resulted in the re-emergence of measles in settings where it has been eliminated especially among groups with a low vaccine coverage (Coombes, 2017; Lo and Hotez, 2017). A lack of antibiotic stewardship, which involves the use of broad spectrum antibiotics, while not clinically indicated, has contributed to the emergence of highly and broadly drug-resistant bacteria (Baur et al., 2017). It is therefore clear that the threat of emerging and re-emerging infectious diseases is unlikely to diminish in the near future. Fortunately technological development in the diagnosis and monitoring of infectious diseases may enable future rapid identification and response to these emerging health threats.

Identifying agents and proving an etiological role in disease

Koch's postulates, which require the presence of an infectious agent in cases with disease, and its absence in those without, and the isolation of the agent in pure cultures, were initially very important to identify infectious etiologies. However, it had limitations. Many organisms cannot be readily grown in cultures. Moreover, the association between infectious agent and disease is not always a simple single agent deterministic association but could be more complex—infections could be present without causing disease or may not be the only (or necessary cause) of a disease. In addition to infection, it may require other factors such as host risk factors to cause disease. In the latter case the infectious agent is not a sufficient cause (Byrd and Segre, 2016; Falkow, 2004). Disease complications may also be the result of chronic infections with a long time lag between infection and disease (O'Connor et al., 2006) which makes it more difficult to directly associate the infectious agent and disease.

An adaptation of Koch's postulates was therefore proposed based on molecular criteria that relied on identification of pathogen sequences (Falkow, 1988). However, complex etiologies require epidemiological evidence that shows an increased risk in individuals who have particular infections compared to those without. In the case of organisms that result in pathologies such as neoplasms, or other delayed complications of infections a combination of molecular and epidemiological evidence is often required. Cervical cancer is almost always the result of infection with oncogenic types of human papillomaviruses (Nicolás et al., 2019) and hepatitis C virus and hepatitis B virus infections are strongly associated with liver cancer. However, other infections such as human herpes virus 8 (HHV8) and Epstein bar virus (EBV) require cofactors before oncogenesis is likely (Mesri et al., 2014).

Proving the association of chronic *Helicobacter pylori* stomach infection with duodenal ulcers and stomach cancer has required epidemiological and intervention studies, in addition to identifying the infection in people with disease (Choi et al., 2018; Preda et al., 2009). Recent developments in human genetics, the analysis of mRNA expression (transcriptomics), the study of protein structure, function and interaction (proteomics), and metabolic pathways (metabolomics) have resulted in increasingly rich data, which help to explain the interaction of host genetics, infections, and the environment. In future, novel approaches to analyze such rich data could allow for a better understanding of cellular level pathways of diseases with complex etiologies. This could also provide novel drug targets to treat these diseases (Karczewski and Snyder, 2018).

Traditional approaches to identifying infectious diseases

The identification and diagnosis of infectious diseases have advanced along with technological development and innovations that involve both biochemistry and engineering. Time-tested or traditional diagnostic approaches have their value and limitations, summarized in Table 2 and discussed below. These methods remain valuable in the discovery and characterization of emerging pathogens and are often complementary to more recently developed molecular assays.

Microscopy and culture-based isolation

Since the discovery of microorganisms by light microscopy and the germ hypothesis developed by Pasteur, Koch, and others, culture media have been developed that allowed for the isolation of bacteria (Blevins and Bronze, 2010; Pasteur, 1881). However, viruses, which are responsible for the majority of emerging infections, were initially elusive as they require living cells (either cell culture or live animals) for growth and laboratory isolation. Viruses are also too small to be held back by bacterial filters or to be identified by light microscopy (Lwoff, 1957). The development of cell culture systems greatly aided the identification of viruses from patient samples (Leland and Ginocchio, 2007). Similarly intracellular bacteria, such as mycobacteria, chlamydia, mycoplasmas, and rickettsiae, are difficult to grow and require special media and often long incubation periods or laboratory animals to isolate them (Doern, 2000). Electron microscopy, which has a much higher resolution than light microscopy, allows the characterization of viral structure and, based on the identified morphology, can then direct further investigations to identify the particular species (Curry et al., 2006).

Immune-based diagnostics

Sera from patients with infections or who recovered from infections proved to be very valuable for diagnosing novel agents and the earliest techniques involved immunodiffusion, precipitation, and counterimmunoelectrophoresis reactions that helped to identify the causative agents (Gocke and Howe, 1970; Stanford, 1973). The underlying principle is the hybridization or binding of antibodies from serum to an antigen. The study of antibody and antigen reactions is often called “serology” as antibodies were initially identified from serum samples. The detection of antibodies would signify prior human exposure to an infectious agent, whereas the detection of antigen using antibodies (often produced in laboratory animals or laboratory cultures) would indicate the current presence of the antigen in a sample or culture isolate from a sample. Different technologies were developed to identify antigen-antibody hybridization, which include immunofluorescence, enzyme immunoassays, and chemiluminescence. Although serological methods were some of the first used for diagnosis of infectious agents, they remain relevant for the diagnosis of novel infectious agents especially when used to determine the prevalence of antibodies as evidence of exposure to a particular pathogen. Serological investigations are applied to determine the extent of exposure of the population to new agents and has been used to assess the extent of COVID-19 spread, since many cases may remain asymptomatic or undiagnosed (Larremore et al., 2021; Metcalf et al., 2016). The study of the presence of antibodies among human populations, referred to as seroepidemiology, is discussed in more detail below.

Table 2 Value and limitations of traditional approaches to identify and diagnose infections.

Method	Value in pathogen identification	Limitations
Bacterial growth media (serum broths and other)	Pure cultures of fast growing bacteria	Cannot isolate viruses or fastidious bacteria
Cell culture methods	Isolation of particular viruses	Many viruses do not show cytopathic effect; and others do not grow in available cell culture systems
Polymerase chain reaction (PCR)	Sensitive detection of low concentration agent	Requires some prior knowledge of the sequence to design primers
Serology	Investigate the presence of antibodies in the community (seroprevalence surveys); determine if newly discovered agent had been circulating in the population before	Indirect evidence by detecting antibodies as part of the immune response, which is variable and could wane after infection. Cross reactivity between related agents (e.g., from the same family such as flaviviruses)

Limitations of traditional diagnostic methods

Despite their value, traditional laboratory diagnostic methods have limitations (Table 2). Cell culture-based isolation of viruses and culture of fastidious bacteria are cumbersome and slow and electron microscopy requires a high pathogen concentration and therefore lacks sensitivity (Lipkin and Firth, 2013). Moreover, for many infectious agents, culture isolation systems are not readily available. The identification of these organisms therefore relies on genetic identification, often referred to as molecular diagnostic methods.

The rapid development in molecular methods

Nucleic acid amplification: The polymerase chain reaction and alternatives

The most important breakthrough in the rapid characterization of viruses and fastidious organisms was the development of the polymerase chain reaction (PCR) by Kary Mullis in 1985 (Mullis et al., 1986; Mullis, 1990) for which he was awarded the Nobel prize in 1993. PCR allows the efficient amplification of DNA to detect low concentrations of infectious agents, directly from biological material, without requiring prior isolation in cell culture. An adaptation of this method, first reverse transcribing RNA to DNA, followed by PCR, called reverse transcriptase PCR (RT-PCR), allowed for the identification of RNA viruses.

Alternatives to PCR are isothermal nucleic acid amplification reactions such as nucleic acid sequence-based amplification (NASBA) or transcription-mediated amplification (TMA), which apply similar principles, loop-mediated isothermal amplification (LAMP) and recombinase polymerase amplification (RPA). The benefit of these isothermal methods is that they may require simpler instrumentation as thermocycling is not required (Gill and Ghaemi, 2008; Li and Macdonald, 2015).

When PCR is followed by nucleotide sequencing it allows for the full characterization of an agent and through phylogenetic analysis a description of its relatedness to other agents. However as PCR amplification requires primers to bind to specific DNA sequences in the template, it requires some prior knowledge of the infectious agent's sequence to allow identification. Therefore, identifying agents that are unexpected or distantly related to known agents offers a challenge and requires adaptation of PCR or alternative approaches for molecular diagnosis (Allander et al., 2005; Reyes and Kim, 1991).

Improvements in biochemistry and engineering, which include automation of extraction and amplification in partially or fully automated closed systems, resulted in nucleic acid amplification technology moving from specialized research laboratories to high-throughput diagnostic laboratories. This had been evident in automated viral load monitoring of HIV and HCV to assess treatment success, and multiplex molecular syndromic diagnosis of respiratory disease, meningitis, and sexually transmitted diseases (Greub et al., 2016). In addition, blood banks make use of molecular methods for blood donor screening to ensure the safety of blood products from donors, who may be in the antibody negative window period (Vermeulen et al., 2009). Recently the importance of high-throughput molecular diagnostics has become most evident, when laboratories have been required to rapidly scale up to test thousands of samples for SARS-CoV-2 by RT-PCR. This was necessary for individual diagnostic and epidemic control purposes (Gorzalski et al., 2020; Opota et al., 2020). In contrast to large high-throughput automated laboratory instrumentation, technological development has also resulted in smaller footprint and easy-to-use, near-patient molecular diagnostic instruments that have become increasingly important in the diagnosis of emerging infectious diseases, at the bedside, or point of care (POC). This has played a major role in the diagnosis of Ebolavirus in field hospital settings and rapid diagnosis of SARS-CoV-2, when required for clinical diagnosis or cohort nursing of infected or uninfected individuals (Raftery et al., 2018; Zhen et al., 2020).

Methods that make use of nucleic acid amplification, primarily with PCR, have overcome some of the limitations of traditional methods. Nevertheless, identification of unknown novel infections from clinical samples poses several challenges for which novel solutions were sought (Table 3).

Dealing with human cellular background

Identifying pathogen genetic material among a much higher concentration of normal human cellular nucleic acid (DNA and RNA) is a challenge. One approach to overcome this is representational difference analysis (RDA) developed in 1993. This approach selectively enriches for DNA sequences that are unique to a particular type of diseased tissue (Lisitsyn et al., 1993). An infectious etiology had long been suspected for Kaposi sarcoma (KS), but it was only when RDA was applied to these tumor tissues that it was

Table 3 Challenges to viral discovery from clinical samples.

Challenge	Impact	Solutions
High concentration of host nucleic acid	Competing host material result in time-consuming process of screening	Pre-analytical <i>Viruses</i> : ultracentrifugation and DNase treatment of samples (viral particles are protected) <i>Subtraction</i> : representational difference analysis (RDA)
Unknown sequence	PCR amplification requires specific primer binding sites	Sequence independent (unbiased) amplification methods; Random PCR; degenerate PCR

Fig. 1 The first Hepatitis C virus (HCV) sequence was obtained from a bacteriophage library in 1989. Representational difference analysis (RDA) facilitated the discovery of human herpes virus 8, in the presence of a high concentration of cellular DNA. The use of consensus primers (targeting conserved regions) and random primers facilitated the discovery of Severe acute respiratory syndrome (SARS) coronavirus in 2003. Sequence independent single primer amplification (SISPA) was a subsequent method that allowed for the non-specific amplification in samples where cellular background was reduced by DNase treatment. Merkel cell associated polyomavirus was identified by linker-mediated PCR, next generation sequencing of mRNA and digital (bioinformatics based) subtraction transcriptome data of normal tissues from that of tumor tissue. Consensus PCR and next generation sequencing of cell-culture supernatant helped to identify SARS-coronavirus 3 (SAR-CoV-2) the cause of Coronavirus disease 2019 (COVID-19).

found that a previously unidentified human herpes virus, called Human Herpesvirus 8 (HHV-8) or Kaposi Sarcoma-Associated Herpesvirus, was present in all KS tissues (Chang et al., 1994). The secret of RDA is that it uses a modified PCR to selectively amplify gene sequences that are present in diseased tissue but absent or at much lower concentration in healthy tissues. It starts with hybridizing a low concentration of amplified products (tester amplicons) from the diseased tissue, ligated to primers, to an excess concentration (driver amplicon) from normal tissues. DNA strands that are unique to the diseased tissue are then preferentially exponentially amplified (Lisitsyn et al., 1993), which facilitates identification of the disease-specific sequences. Subsequently to identifying HHV-8 as the cause of KS, it was found to be associated with Multicentric Castleman's Disease (Soulier et al., 1995) and Primary Effusion Lymphoma (Cesarman et al., 1995). Other viruses identified using RDA are human GB virus (GBV) (Simons et al., 1995), a virus closely related to HCV, but which appears nonpathogenic, and TT virus (TTV) (Nishizawa et al., 1997), from the family Anelloviridae, which is commonly found in blood and is of uncertain significance. Despite the value of RDA, it is very cumbersome, whereas some recently developed biochemical methods are faster and more practicable (Fig. 1).

Unbiased amplification methods

DNase Sequence-Independent Single Primer Amplification (DNase-SISPA) was used to allow nonspecific amplification of viral RNA or DNA from serum, which enabled the identification of human parvovirus 4 (Jones et al., 2005). In short, filtered plasma samples were treated with DNase to remove human DNA, whereafter viral RNA and DNA were extracted. Thereafter RNA was reverse transcribed and complementary DNA (cDNA) synthesized with random primers, followed by restriction endonuclease digestion of viral DNA or double-stranded DNA, reverse transcribed from RNA, and adaptor ligation to allow nonspecific amplification, cloning, and sequencing. A similar approach: Virus Discovery based on cDNA-AFLP (Amplified Fragment Length Polymorphism) (VIDISCA) was used to discover Coronavirus NL-63 in 2004. This method starts with blood plasma, serum, or culture supernatant. Cellular material and mitochondria are first removed by centrifugation, followed by DNase treatment to digest mitochondrial or cellular DNA present in cell fragments, whereas nucleic acid in viral particles remains protected. Viral nucleic acid is then isolated and viral RNA is reverse transcribed to cDNA, followed by second strand synthesis. Double-stranded DNA (either directly from viral DNA or from reverse transcribed RNA) is digested with restriction enzymes, anchors are ligated, which contain primer binding sequences. This is followed by PCR amplification and finally by nucleotide sequencing providing nucleotide sequences from an unknown agent, without requiring any prior sequence knowledge (Van Der Hoek et al., 2004).

Improvements in sequencing technology

First-generation sequencing

The first widely adapted sequencing method was the Maxam and Gilbert technique which relied on chemical treatment generating breaks in a small proportion of DNA strands, separately for each of the four nucleotides. Each of these separately cleaved products is then separated into individual fragments with polyacrylamide gel electrophoresis (Maxam and Gilbert, 1977). Fred Sanger developed a method, which later largely replaced the Maxam and Gilbert method. This relies on DNA polymerase incorporating a mix of normal and chain terminating nucleotides during the process of primer extension with complimentary DNA synthesis. As the chain terminating nucleotides are incorporated, fragments of differing lengths are generated, each ending on a respective chain terminating nucleotide (Sanger et al., 1977). Initially the terminating nucleotides were radiolabelled, but once this was replaced by four different fluorescent labels (Prober et al., 1987) it opened the way for automated capillary electrophoresis, which is the version of Sanger sequencing that remains in use today. Each capillary has as single readout, called an electropherogram, which shows the respective nucleotides, in color, incorporated at each position. Scaling up automated Sanger sequencing relied on increasing the number of capillaries run in parallel. This unfortunately increases instrument footprint and despite Sanger sequencing's elegance exposed its limited scalability: in essence each sequencing reaction and capillary, in which electrophoresis takes place, aims to provide one consensus sequence read. The multitude of automated sequencers therefore required for the human genome project highlighted the limitations of automated Sanger sequencing. Making sequencing more scalable therefore required an approach that would allow the simultaneous sequencing of multiple different templates in one reaction. Several different solutions to this have been developed and have been referred to next-generation sequencing (NGS) or massive parallel sequencing (MPS) (Thermes, 2014; von Bubnoff, 2008).

The development of next-generation sequencing

These sequencing methods employ different principles, all to achieve the objective of multiple simultaneous sequencing reactions, which are physically separated and separately detected (Table 4). As NGS evolved, particular methods including PacBio Single Molecule, Real-Time (SMRT) Sequencing, and Oxford Nanopore Technologies (ONT) developed approaches that enabled the sequencing of very long reads of single genomes. Hence, these massive parallel sequencing methods became known as third-generation sequencing or single molecule sequencing (SMS) to distinguish them from shorter read NGS methods.

When used for pathogen discovery, in principle two different approaches can be followed. The one relies on specific enrichment for related pathogens, with a PCR or other amplification method that includes primers that bind to sequences that are conserved across species or genera, which is then followed by sequencing to characterize the pathogen. The second is nonspecific, attempts to detect all possible infectious agents, present in a sample, and relies on nonspecific amplification or direct sequencing of extracted nucleic acid. This is followed by the alignment of these diverse genetic sequences to bioinformatics databases. This latter process is referred to as metagenomics.

Table 4 Overview of next and third generation sequencing methods.

<i>Method</i>	<i>Separation</i>	<i>Chemical principle</i>	<i>Detection</i>
454 sequencing	DNA linked to beads separated on picotiter wells	As the primer extends, pyrophosphate (PPi) is released; ATP is generated and luciferase mediates conversion of luciferin to oxyluciferin	Light is released
Ion Torrent	DNA is separated on beads in micromachined wells	As primer extends, hydrogen (protons) are released.	Semiconductor chip detects change in voltage
Illumina	Oligonucleotides on nanowells capture DNA (bind to adaptors)	Bridge amplification generates clusters. Sequencing by extension of reversible terminating dNTPs	Four dNTPs are tagged with different fluorophores; laser excites fluorophores and fluorescent light is recorded by a digital camera.
PacBio Single Molecule Real-Time (SMRT) sequencing	Flowcell with thousands of transparent bottom picotiter wells: Zero-mode wave guides (ZMW)	Polymerase is immobilized on the bottom of the ZMD and adds fluorescent nucleotides by primer extension	Movie of light signals is detected as sequential bases are added by immobilized polymerase
Oxford Nanopore Technologies	Individual DNA molecules pass through nanopores that bridge a synthetic resistive polymer membrane	Nucleotide bases occupy a nanopore, as they pass through, resulting in a current change	Current changes associated with successive series of bases passing through the nanopore are resolved bioinformatically into a nucleotide sequence.

Applications of next-generation sequencing

The development of NGS and data from the human genome project made a new approach to the discovery of novel agents possible: Merkel cell carcinoma (MCC), a rare but aggressive cause of skin cancer that affects immunocompromised or elderly persons, was identified through digital transcriptome subtraction (DTS) (Feng et al., 2008). In short, RNA libraries from next-generation pyrosequencing were aligned with expected transcriptomes (the transcriptomes representing expected mRNA sequences from transcribed human genes from the National Center for Biotechnology Information (NCBI) databases). Of the remaining (subtracted) mRNA transcripts one was found to match a polyomavirus sequence. Further investigations found this Merkel Cell Polyomavirus (MCPyV) to be integrated in the large majority of MCC tissues (Feng et al., 2008).

NGS has offered a new metagenomic approach to diagnostics and pathogen discovery. Nonspecific DNA amplification involving transposase, used as library preparation, followed by NGS with Illumina, which uses solid-phase bridge amplification, allows the direct sequencing of low concentration DNA libraries (Marine et al., 2011). This unbiased approach was used to identify a novel arenavirus in cluster of three patients who died after receiving solid organ transplantation from the same donor (Palacios et al., 2008). It has also allowed for the unbiased diagnosis of infections in returning travelers (Jerome et al., 2019). These metagenomic approaches have been shown to correlate well with routine diagnostic methods such as multiplex PCR (Graf et al., 2016; Huang et al., 2019) but works best if the viral loads are sufficiently high (Huang et al., 2019; Kustin et al., 2019). Sensitivity may be increased by enriching first for viral sequences with probe capture before next-generation library preparation (O'Flaherty et al., 2018; Wylie et al., 2015, 2018).

Metagenomic NGS nevertheless holds several remaining challenges which hamper its widespread adoption. A challenge of NGS is the computational and bioinformatics needs to assemble sequence reads and match that to existing databases to identify known and possible novel pathogens (Dutilh et al., 2017). Metagenomic NGS also yield information, including viral genome sequences that are of unknown clinical significance, and which could be nonpathogenic, such as anelloviruses. Nevertheless, anellovirus viral loads have been used to monitor the degree of immunosuppression in organ transplant recipients (Wylie et al., 2018).

Another potential use of metagenomic NGS is to identify agents in nonhuman hosts or arthropod vectors before they emerge as human pathogens as part of a One Health Approach: Multiple emerging human pathogens may be of bat origin, such as filoviruses Ebolavirus and Marburg virus, paramyxoviruses (Hendra and Nipah viruses), and coronaviruses (SARS-CoV, MERS, and SAR-CoV-2). Therefore a metagenomics study of bat viruses may be able to identify viruses of possible zoonotic origin before these spread amongst humans (Geldenhuys et al., 2018).

It is clear that improvements in nucleic extraction, amplification, and sequencing have facilitated the discovery and monitoring of new pathogens. Fig. 1 summarizes a few highlights in this development process.

Developments in epidemiological evidence

Molecular epidemiology

Molecular epidemiology is the study of the genetic variation of infectious agents in human populations in terms of its occurrence: in space, by person (age, gender, ethnicity, socio-economic factors and health-related) and occurrence in time. Organisms are sampled to represent human populations and the genetic sequence characterized. Sequences are compared using phylogenetic analysis, which describes the genetic relatedness in phylogenetic trees and ancestral association between variants. This has become an increasingly valuable tool to characterize the distribution of emerging and re-emerging organisms and inform interventions to curb their spread (Holmes, 1998). Improvements in sequencing technology that facilitate rapid sequencing and computing power that allows for the fast and accurate construction of phylogenetic trees have made this increasingly practicable. A few of multiple cases where this has informed public health interventions are discussed below. The sequencing of organisms in different populations, studied in time, by geographic location and according to risk factor exposure has enabled the modeling of the origin of outbreaks, based on the phylogenetic relationships of organisms. The study of how epidemiological processes, immune responses, and evolution shape phylogenetic relationships has been called "phylodynamics." When an infection emerges or is reintroduced, phylodynamic analysis can help to establish the likely geographic origin and whether there are one or multiple origins. The overall diversity and "date stamped" sample collection could be used to calibrate molecular clock models, which can be used to estimate the date of emergence of the most recent common ancestor. This has been used to establish when particular infectious agents entered human populations. From such studies it emerged that HIV-1 has entered human populations likely before 1930 in central Africa (Gryseels et al., 2020; Worobey et al., 2008) and that circulating human coronaviruses infections such OC-43 and NL-63 are likely the result of historic species jumps from bats (Huynh et al., 2012; Vijgen et al., 2005).

Seroepidemiology and sero-archaeology

When an organism is newly identified, it is important to establish whether the infection is truly new or just previously undiagnosed. Historic serum banks could help to determine whether an agent is truly new. This helped to determine that human metapneumovirus, an important respiratory infection in young children, although first identified in 2001, had been present in humans for at least 43 years before (Van Den Hoogen et al., 2001). In contrast, at the time when SARS CoV and SARS-CoV-2 were first detected, it was

apparent that there had been no pre-existing population immunity toward these novel agents (Ip et al., 2004; Takahashi et al., 2020). After SARS-CoV-2 had spread widely and had been classified as a pandemic, seroprevalence studies of SARS-CoV-2, when adjusted properly for diagnostic error, proved to be very useful in assessing population immunity, the risk for local epidemic spread, and the role of asymptomatic spread in transmission (Larremore et al., 2021).

Similarly, the strains involved in historic influenza pandemics have been studied by investigating birth cohorts and assessing the influenza strains to which different age groups have antibodies. The most important antibodies toward influenza are directed against surface proteins, hemagglutinin (H) and neuraminidase (N), which are used for influenza A typing. When pandemic influenza A strains share similar antigens to prior strains, the older strains are often displaced by the new pandemic strain. Human exposure to particular strains is assessed by performing hemagglutinin (H) inhibition and neutralizing antibody studies. Using this approach it was discovered that H3 influenza strains circulated before 1891 and were reintroduced during the “Hong Kong” pandemic of 1968 when influenza A H3N2 emerged (Reichert et al., 2012; Simonsen et al., 2004). During seasonal influenza epidemics, mortality is higher at the extremes of age, in infants and elderly individuals. However during some influenza pandemic years, older individuals showed lower excess mortality as they had been protected by prior exposure to previously circulating strains that had antigens in common with the emerging pandemic strain (Reichert et al., 2012).

Case studies: Identification and monitoring of important emerging and re-emerging pathogens

The technological development required for the detection and monitoring of infectious diseases involves genomics and immunology. The development of NGS with increased computer power and more robust bioinformatic algorithms and mathematical models of evolution have had a major role in detecting and monitoring emerging infections. This coupled with faster automated nucleic acid amplification technology and a robust biotechnology industry, which supplies reagents fast and have developed point of care and large high-throughput instruments, have enabled an increasingly rapid response to emerging pathogens. A few examples, where technology played a role in the detection and response to emerging or re-emerging infections, are discussed below, but there are multiple other examples, which cannot be covered in a single article.

SARS and other coronaviruses

Prior to 2002, the known human coronaviruses 229E and OC43 were associated with mild upper respiratory viral disease. The first time when a coronavirus was associated with severe pneumonia in humans was when an atypical pneumonia, later named Severe Acute Respiratory Syndrome (SARS), emerged in Guangdong Province, China in November 2002. This virus, called “severe acute respiratory syndrome coronavirus (SARS-CoV)” was identified using a combination of established and newer methods. Vero cell culture and electron microscopy on the culture supernatant identified viruses that resembled coronaviruses. Following viral cell culture isolation, different groups, respectively, used consensus PCR primers (designed based on an alignment of known coronaviruses) (Drosten et al., 2003) or degenerate/random primers and DNA microarrays (Wang et al., 2003) which enabled them to amplify and characterize the SARS-CoV genome using Sanger sequencing.

The identification of SARS-CoV has led to an increased awareness of the possible role of coronaviruses in respiratory infections. Subsequently the VIDISCA method, described above, was used to identify human coronavirus NL-63 (HCoV-NL-63) from a 7-month-old child with bronchiolitis and conjunctivitis. HCoV-NL-63 was thereafter found to be a common respiratory pathogen especially in children (Bastien et al., 2005; Ebihara et al., 2005; Kaiser et al., 2005). Thereafter another novel coronavirus, human coronavirus HKU1 (HCoV-HKU1), was identified from a nasopharyngeal aspirate of a 71-year-old man with pneumonia by using conserved coronavirus primers and thereafter using a mixture of conserved and degenerate primers to amplify the full genome and identify the sequence by automated Sanger sequencing (Woo et al., 2005). HCoV-HKU1 was later found in children and found to be occurring worldwide (Esper et al., 2006; Lau et al., 2006). In 2012, a novel coronavirus was isolated from a 60-year-old male patient from Saudi Arabia with pneumonia and renal failure. A pan-coronavirus PCR, based on the method used for the discovery of SARS-CoV (Drosten et al., 2003), was used to amplify the viral nucleic acid, followed by next-generation 454 pyrosequencing to identify sequences of this novel coronavirus. This virus was named Middle East Respiratory Syndrome Coronavirus (MERS-CoV) based on the geographical distribution of most cases. Human infections with the virus have a mortality of around 35%. Although the virus likely originated from bats, dromedary camels were found to be the reservoir host, with zoonotic infection of humans and household, and healthcare infections being important means of transmission (Killerby et al., 2020).

The identification and monitoring of SARS-CoV-2 and its impact on medical interventions

SARS-CoV-2, the etiology of COVID19, was identified using a combination of consensus PCR and NGS (Zhou et al., 2020) and separately by cloning and NGS and Oxford Nanopore Sequencing of viral nucleic acid from culture supernatant (Zhu et al., 2020). Phylogenetic analysis revealed that this virus belongs to the same subgenus of Betacoronavirus as SARS-CoV namely Sarbecovirus (Lu et al., 2020; Zhou et al., 2020).

Identification of genetic variants

SARS-CoV-2 NGS and phylogenetic and phylodynamic analysis allowed for the global tracing of SARS-CoV-2 variants and provided insights into its pandemic dissemination. The presence of multiple lineages at particular locations indicated multiple introductions (Alm et al., 2020; Candido et al., 2020; Tegally et al., 2021). Moreover, displacement of lineages indicated that particular variants having the G614 spike protein mutation were likely more infectious than other variants (Korber et al., 2020). Later data from the United Kingdom showed that a variant, B.1.1.7, with multiple distinguishable mutations had about 70% higher transmissibility than historic lineages (Kirby, 2021; Tang et al., 2021). Similarly, other new variants emerged: B.1.351 in South Africa (Makoni, 2021), P.1 in Brazil (Candido et al., 2020), and B.1.617 in India (Thiagarajan, 2021), which displaced previous variants. Sequencing of these variants detected additional spike protein mutations which raised concerns about vaccine escape and which may explain the circulation of some of these variants in regions that had a high level of population immunity prior to the emergence of these variants (Sabino et al., 2021). Subsequently several studies showed a lower ability of vaccine- or natural infection-induced antibodies to neutralize the B.1.351 and P.1 variants, impacting on the effectiveness of vaccination (Fontanet et al., 2021; Kupferschmidt, 2021). Genomic surveillance has thus become important to understand the transmission dynamics of emerging infections and to inform public health interventions such as vaccination rollout. This has already had impact on the selection of SARS-CoV-2 vaccines that provide better protection against emerging variants. Moreover, vaccine constructs can be adapted to protect against vaccine escape variants. Whereas vaccines elicit a response to several epitopes and immune escape is most likely to be partial, antibody-based biologicals may be most susceptible to such escape mutations. These antibodies have been developed for putative treatment or prevention and act by neutralizing viral infection through binding to the viral receptor-binding domain. Therefore, any changes that impact the antibody-binding epitopes could be adversely affected by such mutations and may render these biologicals ineffective against the emerging variants. Nevertheless, a cocktail of different antibodies targeting separate epitopes may retain effectiveness against emerging variants (Baum et al., 2020).

West Nile virus

West Nile virus, from the genus *Flavivirus*, Japanese Encephalitis serocomplex, had been detected previously in Africa, Eurasia, Europe, and Australia, when it first emerged in New York City in 1999. During the New York outbreak, of 59 cases, who were hospitalized, seven died. West Nile virus is a mosquito-borne virus with birds as the primary hosts (Campbell et al., 2002). Since the New York outbreak, it spread across most of North America (Beasley et al., 2003; LaDeau et al., 2007). Genetic analysis revealed that the strain emerging in New York was most closely related to lineage I, previously detected in Israel (Beasley et al., 2003) but it remains unknown whether it reached the United States via an infected bird or mosquito. Nevertheless the rapid spread of West Nile virus in the Americas shows the risk posed by international trade or travel to introduce arthropod-borne viruses (also referred to as arboviruses) into new territories when susceptible vectors are already present in these regions.

Chikungunya

Chikungunya is a mosquito-borne alphavirus which was first isolated from a Tanzanian patient in 1953. It is associated with fever and arthralgia during the acute presentation and in some individuals arthralgia may persist for months to years. In Africa, the natural hosts are nonhuman primates, whereas human infections are thought to sustain outbreaks in densely populated Asian settings, although monkeys have been found to be infected in Malaysia. There are three viral genotypes: West African, East/Central/South African (ECSA), and Asian (Morrison, 2014). Since 2004 ECSA genotypes increased in geographic range and spread to Indian Ocean Islands, such that by the end of 2005 there were more than a million suspected cases in this region. Therefore, there was a concern that the ECSA genotype could spread to other tropical regions such as the Americas. Then in December 2013, the French National Reference Centre for arboviruses reported that Chikungunya had been detected in the Caribbean Island of Saint Martin. Subsequently it spread to many countries in South and Central America with almost half a million cases by July 2014. Surprisingly molecular epidemiological analysis revealed that the Asian genotype, and not the suspected ECSA genotype, had been responsible for transmission in the Americas (Leparc-Goffart et al., 2014; Morrison, 2014).

Zika virus

Zika virus, a flavivirus, transmitted by *Aedes aegypti* mosquitoes was first described in 1947 in Uganda and was associated with mild human infection in Africa and Asia in the 1960s to 1980s. The first signal of increased global spread was in 2007 when a large outbreak occurred on the island of Yap followed by outbreaks in French Polynesia in 2013 to 2014. Thereafter Zika virus was identified in the Americas with a large outbreak occurring in 2015 in northern Brazil (Grubaugh et al., 2018; Kindhauser et al., 2016). The large outbreaks in the Pacific and Americas provided strong epidemiological evidence, based on geography and timing, that Zika virus infections are associated with congenital microcephaly when women are infected during the first trimester (Brady et al., 2019; Vissoci et al., 2018). Further strong support was provided by a prospective case control study, enrolling 91 infant cases with microcephaly and 173 controls without microcephaly. Zika virus infection is diagnosed by PCR, in the acute phase, or specific neutralizing antibodies after recovery, as IgM antibodies could be cross reactive to other flaviviruses (Landry and St George, 2017). Thirty two (35%) of the cases with microcephaly had Zika virus infection, confirmed with RT-PCR or serology, vs none of the

controls (de Araújo et al., 2018). The rapid spread of Zika virus emphasized the risk of introduction of arthropod borne viruses (called arboviruses) into new geographic settings where their vectors are present, but where there is a lack of population immunity, contributing to rapid spread and a high incidence of human infections. Molecular clock analysis, based on the genetic diversity of the Brazil outbreak, showed that Zika virus had likely been introduced as early as 2013, suggesting that early vector control could have limited the catastrophic spread (Grubaugh et al., 2018). Monitoring of arboviral infections in humans and insect vectors is therefore crucial to allow early detection and timely vector control programs.

Ebola and other filovirus re-emergence: Tracing the source

Filoviruses are associated with systemic illness and viral hemorrhagic fever in humans. The first filovirus to be isolated was Marburg virus in 1967 in laboratory workers who processed blood and tissue samples from African green monkeys (Slenczka and Klenk, 2007). In 1976 two related filoviruses, associated with hemorrhagic fever viruses, were isolated: Ebolavirus (EBOV) in the Congo (then Zaire) and Sudan virus in South Sudan (then Sudan). Before 2013, outbreaks of filoviruses were localized and limited in size, with until then, the largest outbreak being in 2000, involving 425 cases with Sudan virus in Gulu, Uganda. However, from 2013 to 2016 an epidemic spanned Guinea, Liberia, and Sierra Leone, with 28,646 EVD cases and 11,323 deaths. The scale of the epidemic and the duration of sustained human transmission were unprecedented (Spengler et al., 2016). During this outbreak and subsequent monitoring of regional outbreaks, molecular epidemiology came to its own. By December 2013 only 29 Ebolavirus and 65 Marburg full length sequences had been published. Thereafter next-generation sequencing allowed the generation of cumulatively more than 800 complete filovirus genome sequences by 2020 (Di Paola et al., 2020). Molecular epidemiological data provided valuable information about the transmission dynamics and origin of outbreaks and allowed appropriate targeted medical interventions. Targeted EBOV sequencing and unbiased metagenomic sequencing helped to identify natural hosts of viruses from the Ebolavirus and Marburg virus genera. Phylogenetic analysis revealed transmission chains and the presence of super-spreading events, suggesting that targeting these events could dramatically reduce transmission. The persistence of EBOV in semen and the almost identical sequences identified in sexual partners helped to establish sexual transmission as a mechanism by which outbreaks can be reseeded after transmission cycles have apparently been interrupted. Persistence in semen and re-emergence, fueled by sexual transmission, provide a plausible explanation for the epidemic resurgence that had been observed during these outbreaks (Crozier, 2016; Di Paola et al., 2020; Thorson et al., 2021).

Tracing HIV: History and future

A syndrome of immune suppression, with an epidemiology suggestive of a transmissible agent, was first described in men who had sex with men (MSM) from Los Angeles, California and also found in hemophiliacs (Gottlieb et al., 1981, 1983). To distinguish this from primary immunodeficiency, this was named Acquired Immunodeficiency Syndrome (AIDS) (Gottlieb et al., 1983). Then in 1983, the causative virus, later named HIV-1, was isolated by Barré-Sinoussi et al. (1983). Unlike in the United States and Europe, spread in Africa was predominantly through heterosexual exposure and mother to child transmission, with a generalized epidemic and a high incidence, first observed in Central and East Africa (Quinn et al., 1986). Moreover, a serum sample from 1959 from Kinshasa tested positive, indicating a much earlier presence in Africa than the first diagnosis of AIDS (Nahmias et al., 1986). However, it was through the use of molecular clocks, calibrated with early blood samples from Central Africa, that it became clear that HIV likely first crossed the species barrier, and started to spread amongst humans, around the early part of the 20th century. This timing coincided with large colonial population disruptions, mining and urbanization in the then Belgian Congo (Gryseels et al., 2020; Worobey et al., 2008). By studying the relatedness of simian immunodeficiency viruses from chimpanzee subspecies, *Pan troglodytes troglodytes*, it became apparent that they were the source of this cross-species transmission (Gao et al., 1999). Evidence of other chimpanzee viruses in hunters from Central Africa further substantiated that the hunting and slaughtering of chimpanzees could have resulted in a cross-species jump (Calattini et al., 2007).

Whereas HIV-1 caused a global pandemic, the region of high HIV-2 prevalence is restricted to West Africa. Molecular clock analysis revealed that both epidemic HIV-2 subtypes, A and B, were likely transmitted from sooty mangabeys to humans in the first half of the 20th century, with exponential epidemic growth that coincided with the Guinea-Bissau independence war from 1963 to 1974 (Lemey et al., 2003).

Apart from the value of molecular epidemiology to study the history of the HIV-1 pandemic, identifying transmission clusters is an important tool in attempts to end HIV epidemics on country level (Han et al., 2020). Identifying transmission clusters and acting on these by providing additional support services form part of the United States strategy that aims to end HIV transmission by 2030 (Nichols and Kissler, 2020).

Re-emergent poliovirus

Polioviruses belong to Enterovirus C species and are associated with a risk of paralysis of about 1 in 200 to 1 in 1000. There are three poliovirus serotypes: 1, 2 and 3. In 1988 the World Health Assembly resolved to eradicate poliomyelitis (Forty-First World Health Assembly, 1988). Two types of vaccines are used to prevent polio: live oral polio vaccine (OPV) and inactivated polio vaccine (IPV). Although IPV provides effective individual protection against paralytic polio, administering OPV types 1, 2, and 3 (OPV-1, 2, and 3) provide better herd immunity and its use has been essential in limiting community spread and hence OPV use is essential for

poliovirus eradication. However, OPV strains pose a risk of reverting to virulence and could be transmitted onward, classified as circulating vaccine-derived polio virus (cVDPV), which can be differentiated by sequencing from wild-type poliovirus. Therefore the end stage of poliovirus eradication relies on the withdrawal of OPV as the source of cVDPV (Yan et al., 2021). In 2015 and 2019, respectively, wild-type poliovirus 2 and 3 were declared eliminated. Since fewer mutations are required for OPV-2 to revert to virulence than other types, cVDPV had mostly been due to OPV-2. Therefore, to curb the threat of cVDPV, bivalent OPV (bOPV), which lacks OPV-2, replaced trivalent OPV (tOPV) in May 2016. This approach was initially successful, as it reduced the source of cVDPV by the end of 2016. However, from 2017 to 2019, cVDPV started to rebound, as herd immunity toward poliovirus-2 declined. Paradoxically, OPV-2 withdrawal resulted in an increase in cVDPV derived from OPV-2 (cVDPV-2), which had continued to circulate in insufficiently immune populations. This has resulted in the reintroduction of OPV-2 in regions with cVDPV-2 to mop up such outbreaks (Alleman et al., 2020; Chard et al., 2020). Subsequently a new OPV-2 vaccine construct that is more genetically stable and less likely to revert to virulence has been investigated in clinical trials (De Coster et al., 2021). This vaccine may in future help to prevent cVDPV-2.

It is evident that molecular epidemiological investigations of poliovirus have been and would remain essential in targeting medical control measures. An effective eradication effort is reliant on the fast and accurate genotyping of poliovirus from patients and environmental sources and construction of transmission networks by geographical location and time. This is essential in establishing whether strains identified are wild-type or vaccine-derived and to trace the geographic sources of transmission chains. In addition, full genome sequencing can provide valuable information about the role of recombination of vaccine polioviruses with other Enterovirus C genotypes and its role in regaining virulence. Improvements in next-generation sequencing methods are likely to continue to contribute to the success of eradication efforts in providing critical knowledge about the molecular epidemiology of polioviruses (Jorgensen et al., 2020).

Tracing the source of food-borne outbreaks

Listeria monocytogenes (*L. monocytogenes*) is a gram-positive bacterium responsible for listeriosis in humans. It has the ability to survive in food production plants, when disinfection is insufficient (Gandhi and Chikindas, 2007). Whole genome sequencing of *L. monocytogenes* provides a more accurate classification of types than prior methods such as pulse field gel electrophoresis (PFGE). Moreover phylogenetic analysis could identify outbreak clusters and provide accurate molecular data to trace the source of an outbreak (Lüth et al., 2018).

Noroviruses are highly infectious, environmentally stable, and antigenically diverse feco-orally transmitted viruses that belong to the family *Caliciviridae* and are some of the most important causes of large gastroenteritis outbreaks associated with food vendors, hospitals, cruise ships, and large events. Molecular epidemiology has been useful in identifying the source and transmission dynamics of norovirus infections. Moreover monitoring global diversity and identifying conserved antigenic domains and antibodies that are cross-protective, between strains, may be useful for vaccine development efforts (Hasing and Pang, 2021).

Ribosomal RNA and metagenomics

16S rRNA PCR and sequencing have been used for bacterial metagenomics in environmental and biological samples and have enabled the diagnosis of novel bacteria (Woo et al., 2008), and increased the detection of known bacteria (Cummings et al., 2020), when not clinically suspected. It may be particularly useful when working with fastidious or slow growing organisms as it could provide a fast and unbiased diagnosis. This approach has also been used to detect unexpected bacterial species in brain abscesses (Al Masalma et al., 2009). However, cost and optimal workflow are current constraints. The faster result generation with ONT third-generation sequencing, compared to other next-generation sequencing methods, may increase the utility of 16S rRNA PCR and sequencing, especially if the costs of sequencing can be further reduced and if sequencing accuracy of these novel methods improves further in the near future (Heikema et al., 2020).

As ticks are important vectors of bacterial and viral disease, metagenomic microbiome analysis of ticks for potential bacterial pathogens is important in identifying the risks for human infection, even before human outbreaks might occur. PCR amplification and sequencing of 16S rRNA have been used to identify multiple bacteria belonging to the families *Rickettsiaceae*, *Enterobacteriaceae*, and *Pseudomonadaceae* (Lambert et al., 2019; Sperling et al., 2017). A similar approach also allows for the metagenomic identification of tick-borne bacteria in blood from patients (Kingry et al., 2020; Rodino et al., 2021).

Pan-fungal primers selected in the internal transcribed spacer (ITS) of ribosomal RNA are useful for fungal metagenomics in environmental and biological materials. Fungal infections of hospitalized patients have often been shown to have an environmental origin and identifying the source requires ecological sampling. Drug-resistant *Candida auris* has been associated with serious blood infections in hospitalized patients (Prestel et al., 2021), but the likely source has not been known. Recently, ITS primers for fungal metagenomics were used to identify *Candida auris* in coastal wetlands of the Andaman islands (Arora et al., 2021). It is not yet known, however, if these wetlands are the main natural reservoir of *Candida auris*.

Monitoring infectious agents for drug resistance

Next-generation sequencing could be applied to viruses, bacteria, or parasites and be especially useful to detect novel mechanisms of drug resistance. NGS genome sequencing (WGS) of *Plasmodium falciparum* was able to identify candidate genes involved in

artemisinin resistance, which is an essential drug in malaria treatment and prevention (Ariey et al., 2014). Despite some workflow challenges, NGS is also gaining traction for HIV drug resistance genotyping, as it is more sensitive for low frequency drug resistance variants (Ji et al., 2020). Although the prevalence of Mycobacterium tuberculosis (MTB) is low, in many industrialized countries, it is a re-emerging pathogen in impoverished and resource-limited settings and a high incidence has been seen in settings with a high HIV prevalence. The use of genome capture methods to concentrate MTB from sputum samples, which contain a lot of host DNA, improves efficiency of WGS of MTB (Brown et al., 2015). Whole genome sequencing of MTB has several important applications: it can be used to identify drug-resistant lineages (Oppong et al., 2019), understand the molecular epidemiology of MTB to enable targeted preventions, and investigate the molecular mechanisms of new drugs, which have been recently licensed for MTB treatment (Ikettleng et al., 2018). Considering the multiple drug resistance mechanisms, WGS will likely become increasingly valuable for the rapid identification of drug resistance against second-line drugs in case of multiple drug-resistant (MDR) and extensively drug-resistant (XDR) MTB strains and to investigate drug resistance to novel MTB drugs (Faksri et al., 2019). The same principles apply to investigating phylogenetic relationships of gram-negative and gram-positive bacteria, associated with hospital associated drug resistant outbreaks, and could help to understand the transmission dynamics for the purpose of targeted interventions that would limit nosocomial spread of highly resistant bacteria (Gröschel et al., 2020; Mahmoud et al., 2020; Quainoo et al., 2017).

False findings: Associations with chronic fatigue, prostate cancer, and XMRV

The high sensitivity of molecular methods such as PCR that is based on amplification of DNA increases the risk of false findings. Investigations that aim to discover novel disease associations of infectious agents should ensure that there are appropriate controls that would detect contamination and that cases and controls are treated the same. A novel agent, Xenotropic MLV-related Virus (XMRV), was identified in 2006 and was soon associated with chronic fatigue syndrome (CFS) (Lombardi et al., 2009) and prostate cancer (Schlaberg et al., 2009). However these findings could not be reproduced by others, even when including the same patients; and there was evidence of contamination with identical MLV sequences (Kearney et al., 2012) likely originating from reagents used prior to PCR (Erlwein et al., 2011; Kearney et al., 2012). Similarly, contamination of cell cultures used in prostate cancer research with murine viruses was the likely source of the artefactual association of XMRV with prostate cancer (Das Gupta et al., 2012; Schlaberg et al., 2014).

Conclusion: Identifying and monitoring emerging infections now and in the future

The development of metagenomics methods that allow for the unbiased discovery of infections in humans, the environment, zoonotic hosts or vectors, has the potential to revolutionize pathogen discovery. Moreover improvements in sequencing technology with next-generation sequencing and more recently long-read third generation sequencing have decreased the time from the first identification to full characterization of genomes of newly discovered infectious agents. This is probably most evident in the rapid full characterization and international sharing of the full SARS-CoV-2 genome a few weeks after its discovery. Without such speed of SARS-CoV-2 characterization the fast development of diagnostic tests and the fastest ever development and approval of vaccines, within a single year, would not have been possible.

It has also become apparent that nonhuman mammal hosts are the source of many emerging infections. Molecular epidemiological studies and molecular clock models have shown that HIV originated from primates and that bats host many viruses of concern that have either historically crossed the species barrier or which in future could result in pandemic spread. It is therefore important that the monitoring for pandemic threats involves a One Health Approach, which combines veterinary and human health and which includes the investigation of arthropod vectors of infectious disease.

Globalization has resulted in a higher level of interconnectedness. Moreover high population density and urbanization have increased the risk of rapid spread of respiratory pathogens. Therefore, an infection that emerges in one continent can rapidly spread globally. Nevertheless, it also offers the opportunity for global collaboration in identifying agents of pandemic potential. Such global collaboration, which involves sharing information and technological developments, would remain essential in the rapid identification and response to current and future emerging infectious diseases and pandemic threats.

Introduction

Infectious diseases are still a leading cause of death and morbidity worldwide. Discovering effective treatments has always been a major concern. Following Alexander Fleming's discovery of penicillin in 1928, antibiotics have evolved significantly in curing infectious diseases (Bennett and Chung, 2001). More than 100 different types of antibiotics have been found to date. Antibiotics act through the inhibition of protein synthesis, DNA disruption, and cell wall biosynthesis. While the development of antimicrobials has significantly decreased infectious disease mortality and morbidity, at least in the developing world, the rise of antimicrobial resistance threatens to undo these gains (Dong et al., 2007; Livermore, 2004; Williams, 2002). The World Health Organization has warned that infectious diseases may become incurable due to elevated levels of multiple drug resistant pathogens. However, the development of new technologies has taken a big step toward new therapies. In this regard, T cell therapies, cytokine therapy, monoclonal antibodies, and immune checkpoint blockade, have opened up a new path for the treatment of infectious diseases as well as immunological disorders that will be reviewed in this chapter.

Inflammatory response: A process toward pathogen elimination and establishing homeostasis

Disease development is not solely the result of uncontrolled microorganism reproduction, but the inflammatory response induced by some infections is frequently the cause of tissue damage and death. Inflammatory responses play an important role in the development of chronic infectious diseases as well as many immune-mediated disorders. Therefore, we will first provide an overview of the inflammation and immunological responses that occur during infection, followed by a description of the therapies that are commonly employed to modulate this process.

Inflammation

Inflammation is the reaction of the body to damaging stimuli like infections, damaged cells, poisonous chemicals, or irradiation, and it works by eliminating injurious stimuli and starting the healing process (Ferrero-Miliani et al., 2007). Although cellular and molecular events during inflammation could provide tissue homeostasis, uncontrolled inflammatory responses contribute to the progression of acute inflammation to chronic inflammation, resulting in the development of several types of chronic inflammatory disorders (Zhou et al., 2016).

Local immunological, vascular, and inflammatory cell responses to infection or damage cause pain, heat, redness, swelling, and loss of tissue function. In addition, vascular permeability, recruitment and accumulation of leukocytes, and the release of inflammatory mediators such as cytokines, chemokines, prostaglandins, leukotrienes, and acute phase proteins (APPs) are all important events that occur throughout the inflammatory phase (Ferrero-Miliani et al., 2007, Takeuchi and Akira, 2010, Chertov et al., 2000).

Initiation of inflammatory responses primarily requires the recognition of detrimental stimuli by components of the immune system. In general, both innate and adaptive immune systems are involved in responding to an antigen. Innate immune cells recognize antigens through pattern-recognition receptors (PRRs) which have specificities for conserved structures expressed by microorganisms (Janeway, 1989; Rezaei et al., 2021). The molecular patterns of the microorganisms which can be identified by the PRRs are referred to as pathogen-associated molecular patterns (PAMPs). In addition to PAMPs, various endogenous molecules known as damage-associated molecular patterns (DAMPs) that are released during tissue damage can also be recognized by PRRs (Brusselle and Bracke, 2014). The PRR families include the NOD-like receptors (NLRs), Toll-like receptors (TLRs), retinoic acid-inducible gene (RIG)-I-like receptors (RLRs), and C-type lectin receptors (CLRs) (Takeuchi and Akira, 2010).

In the adaptive immune system, specific receptors expressed on T and B lymphocytes (T cell receptor [TCR] and B cell receptor [BCR], respectively) are responsible for recognition of and responding to the microorganism's antigens. However, innate immune responses precede adaptive immunity and are required for lymphocyte activation. Activation of adaptive immunity eventually leads to the development of specific responses against pathogens and results in prolonged immunity by producing memory cells.

Once the stimulus is recognized, intracellular signaling pathways including nuclear factor kappa-B (NF- κ B), mitogen-activated protein kinase (MAPK), and Janus kinase (JAK), signal transducer and activator of transcription (STAT) are activated, leading to the production of inflammatory mediators. Releasing these mediators results in the development of an inflammatory environment that, if left uncontrolled, can lead to tissue damage and even cell death. A variety of inflammatory mediators such as inflammatory cytokines (e.g., interleukin-1 β [IL-1 β], interleukin-6 [IL-6], and tumor necrosis factor- α [TNF- α]), chemokines, eicosanoids, and vasoactive amines can be produced by tissue resident immune cells such as macrophages, dendritic cells, and mast cells, or by infiltrated leukocytes from blood circulation that all ultimately lead to promote response against a certain pathogen. Monocytes, macrophages, and dendritic cells are the important immune cells that release inflammatory cytokines such as IL-1 β , IL-6, TNF- α , colony stimulating factors (CSF), and interferons (IFNs). These molecules increase vascular permeability and enhance leukocyte recruitment to the site of infection or injury. In this regard, inflammatory response leads to the expression of cell-adhesion molecules on the endothelial cells, resulting in the promotion of leukocyte binding and their migration from the blood stream to affected tissue, a mechanism known as "extravasation." Neutrophils are the first cells that are attracted to the site of inflammation or injury. After that, monocytes, natural killer cells (NK), mast cells, and lymphocytes (T and B cells) are recruited (Rezaei et al., 2021).

Cells involved in inflammation

Neutrophils are the most common innate immune cells in the body, and they serve as the body's first line of defense against infection. Neutrophils quickly migrate from the bloodstream to injured tissue in response to infections. CXCL8, as a chemotactic factor, is critical for their recruitment. By phagocytosis and releasing cytotoxic granules, these cells play a crucial role in the initiation of the inflammatory response (Rosales, 2018).

Monocytes can differentiate to macrophages and dendritic cells (DCs). Monocytes and macrophages are the main components of the innate immune system which play several inflammatory and regulatory roles, including phagocytosis, cytokine production, antibody-dependent cell cytotoxicity (ADCC), antigen presentation, T cell proliferation and activation, and tissue repair leading to pathogen elimination and tissue homeostasis. DCs are considered as important cells which can make a linkage between innate and adaptive immune responses. These cells possess important functions during inflammation, such as pathogen uptake by phagocytosis or pinocytosis, antigen presentation and T cell activation, and cytokine production.

Mast cells have main functions in response to bacterial infections and certain parasitic infections. These cells are mainly involved in allergic reactions. Mast cells produce a variety of cytokines, including IL-1, IL-6, TNF, IL-4, IL-5, IL-13, and chemokines MCP-1, MIP-1, RANTES. These molecules promote inflammatory responses leading to pathogen killing, increased phagocytosis, and enhanced adaptive immune responses. In addition, granule exocytosis can result in the pathogenesis of several allergic disorders causing hypersensitivity symptoms (Abraham and Arock, 1998).

NK cells have an important cytotoxic role, especially against virus-infected cells and cancerous cells (Stabile et al., 2017). NK cells can exert their cytotoxic functions on the target cells by releasing cytotoxic granules containing perforin and granzyme (Topham and Hewitt, 2009).

Eosinophils and basophils are other cells involved in innate immune responses. Eosinophils play a critical role in defense against parasitic infections and allergic reactions and also in tissue homeostasis. Upon stimulation by pathogens, these cells can produce several inflammatory cytokines and lipid mediators, including IL-6, IL-2, IL-8, TNF- α , INF- γ , TGF- α/β , GM-CSF, platelet-activating factor (PAF), leukotriene C4 (LTC4), and matrix metalloproteinases (MMPs) (Shamri et al., 2011). Basophils are also involved in allergy responses and hypersensitivity reactions. These cells release granules containing histamine, heparin, serine proteases, leukotrienes, and prostaglandins in response to stimuli (Chirumbolo et al., 2018).

An overview of therapeutic approaches to treat infectious diseases and immunological disorders

Anti-cytokine therapy

Cytokines regulate inflammation and modify the immunological response to infection or inflammation. However, uncontrolled and excessive production of inflammatory cytokines can result in tissue damage and death (Czaja, 2014; Liu et al., 2016a,b). Specific antagonists can target a variety of cytokines involved in inflammation or their receptors. TNF inhibitors are one of the most effective of these therapies. The soluble form of TNF receptor and anti-TNF antibodies are biological TNF inhibitors that by binding to TNF have the potential to neutralize it. These agents have been shown to be effective in treating many autoimmune diseases, including rheumatoid arthritis (RA), psoriasis, and Crohn's disease. Infliximab (Remicade[®]), adalimumab (Humira[®]), golimumab (Simponi[®]), and certolizumab (Cimzia[®]) are important anti-TNF monoclonal antibodies (mAbs) approved for treating autoimmune disorders (Senolt, 2019).

In addition to TNF, the inflammatory cytokine IL-6 plays an important role in the initiation and development of immune responses in autoimmune diseases like RA. Several antibodies have been developed that can bind to IL-6 or its receptor and effectively neutralize it. Tocilizumab (Actemra[®] or RoActemra[®]) is a humanized anti-IL-6 receptor mAb that binds to both soluble and membrane-bound IL-6 receptors. Its effectiveness in the treatment of RA, systemic lupus erythematosus (SLE), systemic juvenile idiopathic arthritis, Castleman's disease, juvenile dermatomyositis (DM), vasculitis, and juvenile scleroderma is currently being investigated (Jung et al., 2018). Sarilumab (Kevzara[®]) is a human IgG1 mAb that targets the IL-6 receptor and has been developed to treat RA (Lamb and Deeks, 2018). Inhibitors of IL-6, such as sirukumab, olokizuman, and clazakumab, are also currently being developed for the treatment of inflammatory diseases (Sadeghalvad and Rezaei, 2021).

IL-1 is another inflammatory cytokine that induces and regulates inflammatory responses. IL-1 inhibitors such as canakinumab and IL-1 receptor blockers such as anakinra have been shown to be effective in treating a variety of inflammatory disorders (Migliorini et al., 2020; Dinarello et al., 2012). Canakinumab (ACZ885, Ilaris[®]), an anti-IL-1 β IgG1 mAb, was approved in 2009 for the treatment of cryopyrin-associated periodic syndrome (CAPS). Following that, this mAb was approved for use in other inflammatory diseases, including familial Mediterranean fever (FMF), TNF receptor associated periodic syndrome (TRAPS), hyperimmunoglobulin D syndrome (HIDS), and mevalonate kinase deficiency (MKD) (Dhimolea, 2010). Anakinra is an IL-1RI antagonist that inhibits IL-1 α and IL-1 β from interacting with IL-1R1, leading to a reduction in inflammatory response and tissue damage (Lamb and Deeks, 2018).

IL-17 is a key cytokine that possesses several functions, including T cell activation and neutrophil recruitment. This cytokine can mediate innate immune responses against pathogens, especially bacterial and fungal infections, and may play a role in the development of inflammatory disorders such as RA and psoriasis. Secukinumab (Cosentyx[®]) is an IgG1 mAb that can bind to IL-17A. This mAb is approved for the treatment of psoriasis and ankylosing spondylitis. Ixekizumab (Taltz[®]) and Brodalumab (Siliq[®] or Kyntheum[®]) also neutralize IL-17 and were developed for the treatment of plaque psoriasis. Targeting another cytokine, IL-23, has also shown promising results for treating plaque psoriasis. This cytokine mediates differentiation and activation of Th17 cells. Interleukin-23 inhibitor antibodies include Tildrakizumab (Ilumya[®]), Guselkumab (Tremfya[®]), and Risankizumab (SKYRIZI[®]) (Abdo and Tye, 2020; Kuwabara et al., 2017).

Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are medications that are commonly used to alleviate pain, decrease inflammation, and reduce high fever. NSAIDs are particularly useful for treating arthritic symptoms such as joint pain, inflammation, and stiffness. These drugs work by inhibiting cyclooxygenase (COX), the enzyme responsible for the production of prostaglandins (PGs). There are two COX isoenzymes that mediate prostanoids (PGs and thromboxane [Tx]) synthesis. COX-1 is a constitutive enzyme that produces PGs and Tx_{A2} which protect the stomach and kidneys from injury and can regulate physiological functions of the gastrointestinal, vascular and renal systems. COX-2 is induced by inflammatory stimuli like cytokines, and it generates PGs that contribute to inflammation-related pain and fever (Vane and Botting, 1998). Aspirin, ibuprofen, and naproxen are some examples of NSAIDs. Coxibs (e.g., Celecoxib, Etoricoxib, Parecoxib, Rofecoxib, Valdecoxib) are also NSAIDs that are used to treat pain and inflammation in several types of acute and chronic diseases. When compared to traditional NSAIDs, these medicines are associated with a lower risk of gastroduodenal ulcers and fewer clinically relevant complications (Gatti and Adami, 2010).

Disease-modifying antirheumatic drugs (DMARDs)

DMARDs are a class of medicines used to treat RA. In addition, other autoimmune disorders such as ankylosing spondylitis, psoriatic arthritis, and SLE are all also treated with some of these medications. DMARDs act to relieve pain and inflammation and maintain joint structure and function. These drugs are frequently used in combination with NSAIDs to reduce joint injury. Methotrexate, sulfasalazine, hydroxychloroquine, and leflunomide are the most frequent traditional DMARDs. The use of azathioprine and other medicines is usually less common. Methotrexate was first used to treat cancer patients as a chemotherapy drug. This drug reduces inflammation and joint damage when taken at much lower dosages for RA and other rheumatic disorders. Methotrexate inhibits dihydrofolate reductase (DHFR), an enzyme involved in tetrahydrofolate production. As a result, the production of DNA, RNA, thymidylates, and proteins is inhibited (Rajagopalan et al., 2002). It has been shown that methotrexate can interfere with the binding of IL-1 β to its receptor (Brody et al., 1993).

The mechanism of action of sulfasalazine is still unclear, but it is likely to reduce inflammation by inhibiting prostaglandins (Deglin et al., 2014; Plosker and Croom, 2005). Sulfasalazine has been effectively used in treating inflammatory bowel diseases, including ulcerative colitis and Crohn's disease, in addition to inflammatory arthritis such as psoriatic arthritis (Plosker and Croom, 2005).

Hydroxychloroquine was first developed as a treatment for malaria, but it was subsequently shown to be effective in alleviating arthritic symptoms. It is also commonly used to treat SLE. The mechanism of action of this drug in the treatment of inflammatory diseases is still unclear. Its antirheumatic effects are thought to be due to their interference with "antigen processing" in macrophages and other antigen-presenting cells (APCs). Importantly, the acidic pH in the cytoplasmic compartments of an APC is vital for digestion of the antigenic proteins and then assembling the peptides into MHC class II molecules. It has been shown that chloroquine and hydroxychloroquine can raise the pH of intracellular vacuoles, disrupting the antigen presentation process (Fox, 1993).

Leflunomide is another immunosuppressive drug that can reduce inflammation through inhibition of a mitochondrial enzyme named dihydroorotate dehydrogenase (DHODH). DHODH mediates de novo synthesis of the pyrimidine ribonucleotide uridine monophosphate (rUMP). It has been proposed that leflunomide can exert its effect by inhibiting the development of activated lymphocytes. Leflunomide has been used to treat patients with RA and psoriatic arthritis (Fox et al., 1999).

Azathioprine is an immunomodulator drug that exerts its effect by inhibiting purine synthesis, resulting in impaired synthesis of nucleic acids RNA and DNA. It can be used in a variety of disorders, such as RA, SLE, Crohn's disease, ulcerative colitis, and granulomatosis with polyangiitis. In addition, it has been used in kidney transplants to prevent rejection (Axelrad et al., 2016; Singer and McCune, 2017; Jordan and D'Cruz, 2016).

Corticosteroids

Glucocorticoids (corticosteroids) suppress a wide spectrum of immunological responses. Glucocorticoids are extremely effective in controlling many of the acute disease symptoms of inflammatory and autoimmune disorders due to their inhibitory actions on numerous kinds of immune cells, such as lymphocytes, dendritic cells, and myeloid cells (Chatham and Kimberly, 2001; Coutinho and Chapman, 2011). They're commonly used to treat a variety of acute and chronic inflammations, including psoriasis, RA, multiple sclerosis, inflammatory bowel disease (IBD), and eczema. Glucocorticoids can also be used in some leukemias and after organ transplantation to prevent organ rejection (van Staa et al., 2000). On the other hand, long-term usage of oral glucocorticoids has been linked to significant adverse effects such as osteoporosis, metabolic illness, and an increased risk of cardiovascular disease. Glucocorticoids prevent vascular permeability and leukocyte infiltration to the sites of inflammation. They inhibit transcription of genes associated with inflammatory responses, such as NF- κ B and AP-1 and down regulate the expression of inflammatory cytokines, chemokines, and cell adhesion molecules (Smoak and Cidlowski, 2004). In infectious diseases, glucocorticoids can be used for alleviating constitutional symptoms and for cardiovascular effects as an anti-inflammatory agent. Short-term steroid treatment can certainly decrease the morbidity in diseases with extremely severe constitutional symptoms, such as typhoid fever, brucellosis, and tuberculosis (Dale and Petersdorf, 1973).

Signal transduction inhibitors

The identification of cell-signaling pathways that are active during inflammation has made significant progress, and numerous targets have emerged, particularly in pathways involving the transcription factor NF- κ B and mitogen-activated protein kinases (MAPKs).

Targeting the NF- κ B signaling pathway

The light-chain gene in B cells was the first gene to be shown to be influenced by the NF- κ B signaling pathway. IL-1 and TNF were subsequently shown to be activated by this signaling pathway (Sen and Baltimore, 1986). Currently, it has been found that a variety of inflammatory mediators can be regulated by NF- κ B including several cytokines, chemokines, COX2, cell adhesion molecules, acute phase proteins, inducible nitric oxide synthase (iNOS) and anti-apoptotic proteins. On the other hand, several receptors, such as the IL-1 receptor (IL-1R), TNF receptor family members, NOD-like receptor (NLR), Toll-like receptors (TLR), and lymphocyte receptors (TCR and BCR) are all important for stimulating the NF- κ B signaling pathway and triggering inflammation process

(O'Neill, 2006). This pathway consists of a number of important mediators, such as the scaffold protein NF- κ B essential modulator (NEMO) and the two kinases inhibitor of NF- κ B (I κ B) kinase 1 (IKK1) and IKK2. It has been shown that NEMO inhibitor named NEMO-binding domain (NBD) peptide can suppress acute inflammation *in vivo*. Therefore, it has been proposed that the NBD peptide has the potential to be utilized as a therapeutic treatment for inflammatory disorders (di Meglio et al., 2005). Several NF- κ B inhibitors have been approved for treating inflammatory responses, including Oxycodone/Ibuprofen (Combunox®), Bortezomib, Pranlukast, Gabexate, Sulindac, Silibinin, and Sulfasalazine (Ivanenkov et al., 2008).

Targeting the JAK/STAT pathway

The Janus kinase/signal transducer of activated transcription (JAK/STAT) pathway is triggered by several cytokines, resulting in enhanced expression of target genes. JAKs are tyrosine kinases that are stimulated by cytokines and interferons and then activate the STAT family of transcription factors. Because of its specific expression in T cells and activation by IL-2, JAK3 has sparked the most therapeutic development interest among the four JAKs. CP-690550 is a JAK3 inhibitor whose efficacy has been shown in the inhibition of graft rejection in a primate model (Changelian et al., 2003).

Targeting T cell signaling pathway

Several immunosuppressant medicines target T lymphocyte signaling and have shown effectiveness in autoimmune disorders. Cyclosporin and FK506 are the main immunosuppressive agents that inhibit calcineurin. Since calcineurin can dephosphorylate and activate an important transcription factor of T cells named nuclear factor of activated T cells (NFAT), its inhibition can impede NFAT activation, resulting in decreased IL-2 production as a vital T cell growth factor. Another calcineurin inhibitor, ISA247 (Isotecnika), has been shown to be effective in psoriasis (phase II trial) (Bissonnette et al., 2006; O'Neill, 2006).

FTY720 or Fingolimod, is an immunomodulating medication that exerts its effect by modulating the sphingosine-1-phosphate receptor (S1PR). This drug has been used effectively to treat patients with multiple sclerosis. Fingolimod causes internalization of the S1PR and therefore prevents infiltration of lymphocytes that results in suppression of the autoimmune reaction (Brinkmann, 2009).

Rapamycin is another immunosuppressive drug that can target a protein in the T cell signaling pathway named mammalian target of rapamycin (mTOR), a member of the PI3K-regulated protein kinases (Young and Nickerson-Nutter, 2005). mTOR inhibition leads to arrest of the cell cycle in G1. Rapamycin has been used to prevent rejection of transplanted organs as well as for treating autoimmune disorders like arthritis. Other mTOR inhibitors include Everolimus and Temsirolimus, which have been shown to be effective in inflammatory disorders (Dancey, 2005).

Targeting toll-like receptor (TLR) signaling pathway

TLRs are a family of innate immune receptors composed of several members, including TLR1 to TLR10 in humans, with the ability to recognize pathogens or damage associated molecular patterns. Several protein kinases are involved downstream of TLRs, especially the IL-1 receptor-associated kinase (IRAK) family, TBK-1, and MyD88. Activation of these downstream pathways results in activation of transcription factors such as NF- κ B and interferon regulatory factor 3 (IRF3) leading to inducing the expression of a variety of inflammatory genes. Thus, TLR signaling pathway suppression has been anticipated to be a useful therapeutic approach for suppressing undesired, disease-associated inflammatory responses. Several types of TLR's antagonists or agonists have been designed to treat inflammatory disorders such as RA, Sepsis, Crohn's disease, Alzheimer, and Parkinson (O'Neill et al., 2009). TLR inhibitors can be categorized as antibodies, microRNAs, nano-inhibitors, oligonucleotides, lipid-A analogs, and small molecule inhibitors (SMIs) (Gao et al., 2017).

Examples of SMIs include TLR4 inhibitor, TAK-242, for treating septic shock, which is in a phase III clinical trial (Matsunaga et al., 2011). Fluvastatin, Simvastatin, and Atrovastatin are other TLR4 inhibitors that have been studied in experimental models (Gao et al., 2017). Chloroquine and hydroxy chloroquine are TLR7/8/9 inhibitors used in RA and SLE (Ruiz-Irastorza et al., 2010). CPG-52364 is another TLR7/8/9 inhibitor in a phase I trial for treating patients with RA and SLE (Lipford et al., 2007).

OPN-305, a humanized IgG4 monoclonal antibody targeting TLR2, has been shown to be successful in inhibiting the production of inflammatory cytokines *in vitro* and in ischemia reperfusion injury animal model (Farrar et al., 2012; Ultaigh et al., 2011). T2.5 is another mAb targeting TLR2 that showed promising results in treating septic shock, cerebrovascular ischemia and cardiac fibrosis in animal studies [Meng et al., 2004]. NI-0101 is a monoclonal antibody against TLR4 that its effectiveness in treating RA is being investigated in a phase I trial (Monnet et al., 2015).

The examples of oligonucleotides include the IRS-954, IMO-3100, and IHN-ODN-24888 (TLR7/9 inhibitors) evaluated in preclinical studies for treating SLE, and IMO-8400 (TLR7/8/9 inhibitor) which is in phase II for treating dermatomyositis and plaque psoriasis. The class of miRNAs includes mir-146a and mir-21 which can target TLR4 and have been evaluated in animal models to treat autoimmune diseases and inflammation, respectively. Eritoran is a lipid A analog targeting TLR4/MD2 that has been evaluated in phase III for treating sepsis, and in animal models for treating influenza infection (Gao et al., 2017).

Cytokine therapies

Susceptibility to infectious diseases might indicate an underlying immune system deficiency. The characterization of the functional effect of a certain defect can lead to new therapeutic approaches for preventing or treating infections. Primary immunodeficiencies (PIDs) are a group of disorders characterized by genetic defects in a component of the immune system resulting in impaired

immune responses. Therefore, patients with PIDs are more susceptible to recurrent infectious diseases. The treatment using cytokines has been used widely to treat specific infections in these patients. In this section, we will review the important cytokines that have been used to treat infections in patients with PIDs.

Granulocyte-colony stimulating factor (G-CSF) has been developed as the first line therapy for patients with severe congenital neutropenia (SCN). G-CSF reduced the frequency and severity of infections (Newburger and Dale, 2013). In addition to SCN, G-CSF has been used for treating infections in Chronic Granulomatous Disease (CGD) (Kimura et al., 1990; Nakajima et al., 1992). Granulocyte-monocyte-colony stimulating factor (GM-CSF) was used to treat pulmonary alveolar proteinosis (Venkateshiah et al., 2006). A patient with recessive caspase recruitment domain family, member 9 (CARD9) deficiency who presented with spontaneous CNS candidiasis was effectively treated with GM-CSF (Gavino et al., 2014). GM-CSF has also shown promising results in treating infections with *S. aureus* in patients with CGD (Martino et al., 2000).

IL-2 is another cytokine that plays an important role in stimulating T cell subsets, NK cells, and macrophages. This cytokine has been used in a variety of PIDs to treat infections. IL-2 therapy has been effectively used to treat sphenoid sinusitis and cutaneous mycosis in patients with common variable immunodeficiency (CVID) (Cunningham-Rundles et al., 1992). In addition, the effects of IL-2 in the treatment of infections (like chronic pulmonary disease, relapsing generalized cutaneous zoster, and cryptococcal meningitis) have also been reported in patients with idiopathic CD4⁺ lymphocytopenia (ICL) (Warnatz et al., 2000; Cunningham-Rundles et al., 1999; Trojan et al., 2009; Sternfeld et al., 2010; Yilmaz-Demirdag et al., 2008).

The effectiveness of IL-7 has been shown in a patient with progressive multifocal leukoencephalopathy (PML). Neurologic status and clearance of JC virus was shown after approximately 4 weeks (Patel et al., 2010).

Interferon Type I is a family of cytokines involved in antiviral immune responses, consisting of IFN- α , IFN- β and other interferons, including IFN- ϵ , IFN- κ , IFN- η and IFN- ω . The treatment of epidermodyplasia verruciformis was one of the first and most common applications of IFN- α in PIDs. Epidermodyplasia verruciformis (EV) is a genodermatosis characterized by a high sensitivity to cutaneous infection caused by the b-HPV virus family, which is otherwise nonpathogenic in humans. Several studies have shown that IFN- α can effectively treat EV (Blanchet-Bardon et al., 1981; Lutzner et al., 1984; Androphy et al., 1984; Anadolu et al., 2001; Gubinelli et al., 2003; Baskan et al., 2006; Silva et al., 2006).

In addition, CVID and ICL were reported to be treated using IFN- α (Vinh, 2014). Using IFN- β has been reported in a patient with X-linked agammaglobulinemia (XLA) who developed chronic enteroviral meningoencephalitis; clinical improvement was shown after using IFN- β (von der Wense et al., 1998).

IFN- γ , a member of type II interferon, has been approved to treat active infections (such as brain fungal abscess, salmonellosis, hepatic abscess) in CGD and malignant osteopetrosis (Ma et al., 2003; Saulsbury, 2001). Disseminated salmonellosis has also been treated in patients with AR IL-12p40 deficiency (Altare et al., 1998). In addition, the management of mycobacterial infections related to IL-12/IFN- γ axis deficiencies has provided the most reported experience with IFN- γ for the treatment of active infections in PIDs (Filipe-Santos et al., 2006).

Antibody therapies

Monoclonal antibodies

In response to antigens, differentiated B cells known as plasma cells secrete antibodies or immunoglobulins. Antibodies are popular molecules with high efficiency in a variety of therapeutic and diagnostic applications due to their great specificity and diversity. In this regard, since the first mAb was authorized in 1986, using mAbs has become a unique approach to targeting antigens in a wide range of diseases. The first mAb authorized by the Food and Drug Administration was Orthoclone OKT3[®] (muromonab-CD3) (FDA) to treat acute transplant rejection (Liu, 2014). mAbs are now the most common type of therapeutic molecule in clinical studies for inflammatory and autoimmune disorders (e.g., RA, SLE, IBD, multiple sclerosis, psoriasis), malignancies (e.g., breast cancer, multiple myeloma, melanoma, leukemia) and infectious diseases (Lu et al., 2020). Therapeutic antibodies against inflammatory cytokines have previously been discussed in the section of anti-cytokine therapy. We are now discussing other monoclonal antibodies used in diseases related to the immune system.

The CD20 antigen is a phosphoprotein found on B lymphocytes that promotes B lymphocyte proliferation and activation by triggering an intracellular signaling cascade. mAbs against CD20 induce B cell death and may impair B cell activity via antibody-dependent cell mediated cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC). Rituximab (Rituxan[®]), a chimeric monoclonal antibody (mAb) that targets the CD20 antigen, was originally authorized for the treatment of lymphomas. In addition, encouraging outcomes have been seen in the treatment of various autoimmune disorders, including RA, SLE, Wegener's granulomatosis, dermatomyositis, refractory immune thrombocytopenic purpura, and autoimmune hemolytic anemia (Sadeghalvad and Rezaei, 2021). Another humanized anti-CD20 antibody, Ocrelizumab (Ocrevus[®]), has been approved for the treatment of the primary progressive form of multiple sclerosis. Ofatumumab is also another anti-CD20 mAb that has shown successful results in patients with multiple sclerosis and RA.

Adhesion molecules have a critical role in leukocyte recruitment, activation, and localization. Therefore, targeting these molecules is thought to be an effective treatment for autoimmune disorders and excessive inflammation (Harjunpää et al., 2019). The first mAb authorized for MS therapy was Natalizumab (Tysabri[®]), a humanized mAb against the cell adhesion molecule $\alpha 4$ -integrin. Natalizumab inhibits leukocyte migration to the central nervous system by preventing the interaction of $\alpha 4$ -integrin with

VCAM-1 expressed on endothelial cells. Crohn's disease is also treated with Natalizumab. Alemtuzumab (Lemtrada®) is a humanized mAb that targets CD52 (also known as COMPATH1), which is expressed on dendritic cells, monocytes, and lymphocytes. Alemtuzumab was authorized for the treatment of multiple sclerosis, chronic lymphocytic leukemia, and organ transplant immunomodulation (Voge and Alvarez, 2019).

Graft-versus-Host Disease (GVHD) is a death-causing complication of bone marrow transplantation. GVHD develops when alloreactive donor T cells engage with major histocompatibility (MHC) molecules in the host, activating the immune system and causing increased cytokine release (Ramachandran et al., 2019). Using molecules that can target T cells may be beneficial in preventing GVHD. In this regard, Anti-CD25 (IL-2 receptor) mAb has been shown to be effective in suppressing T cells (Ji et al., 2005). Daclizumab (Zynbryta®) is another mAb which targets the IL-2 receptor and its use has been linked to a lower incidence of acute renal transplant rejection (Carswell et al., 2001).

Therapeutic mAbs have also been used in patients with asthma. Immunoglobulin E (IgE) levels in the blood play an essential role in the development of allergic asthma, which causes bronchial hyperresponsiveness. Therefore, using mAbs targeting IgE or its receptor can be considered as an effective therapeutic agent in these patients. Omalizumab (Xolair®), a humanized monoclonal antibody, prevents IgE from attaching to its receptor (FcR1) and has been shown to be effective in individuals with severe asthma (Loureiro et al., 2018). Dupilumab (Dupixent®), a monoclonal antibody targeting the IL-4R receptor, has been authorized for the treatment of moderate to severe asthma (Thibodeaux et al., 2019). Other cytokines that can be targeted in asthma include IL-5, IL-13, and IL-9. Benralizumab, Mepolizumab, and Reslizumab are approved mAbs for treating eosinophilic asthma (Khorasanizadeh et al., 2016). IL-13 can be neutralized by Tralokinumab and Lebrikizumab monoclonal antibodies. MEDI-528 is an anti-IL-9 monoclonal antibody that can suppress mast cell function in the pathogenesis of asthma (Oh et al., 2013).

Intravenous immunoglobulin G (IVIg)

IVIg is a therapeutic compound prepared from plasma collected from several donors containing opsonic and neutralizing IgG (mainly IgG1 and IgG2). However, in addition to IgG, other isotypes of immunoglobulins, importantly IgA may be found in IVIg. IVIg has been used to treat a variety of primary and secondary immunodeficiencies for more than two decades. IVIg is currently a common treatment option for most antibody deficits. In patients with severe combined immunodeficiency, X-linked agammaglobulinemia (XLA), X-linked hyper-IgM, common variable immunodeficiency (CVID), Wiskott-Aldrich syndrome, and selective IgG class deficiency, IVIg is routinely administered. IVIg has been utilized in a variety of autoimmune diseases (e.g., autoimmune neutropenia, autoimmune hemolytic anemia, polymyositis, SLE, Crohn's disease) and inflammatory disorders since the preliminary work by Paul Imbach, who found a favorable effect in idiopathic thrombocytopenic purpura (Bayry et al., 2003). On the other hand, using IVIg has been shown to be effective in several bacterial and viral infections, including respiratory infections (e.g., *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*), diphtheria, pertussis, tetanus, *Clostridium botulinum*, *Clostridium difficile*, newborn sepsis, hepatitis A/B/C, HIV, varicella zoster, and measles (Katragkou et al., 2018). IVIg exerts its immunomodulatory effects by several mechanism, including ADCC, inhibiting Fc receptors on effector cells, inhibition of lymphocyte proliferation, induction of inhibitory FcγRIIB receptors, and neutralizing microbial toxins (Bayry et al., 2003).

Convalescent plasma (CP) therapy

A growing body of research shows that treatment using plasma containing antibodies from a recovered patient is beneficial for a variety of viral respiratory diseases. This therapy is thought to work primarily by neutralizing specific pathogens (Garraud et al., 2016). Antibodies that bind to pathogens prevent the pathogen from entering host cells and improve pathogen clearance through mechanisms including phagocytosis, ADCC, and CDC. On the other hand, other active factors present in CP, such as anti-inflammatory cytokines, natural antibodies, and pentraxin, can also play an effective role in defense against pathogens (Garraud et al., 2016). An improved survival rate has been shown in patients with SARS-CoV related pneumonia and Influenza A (H1N1) who were treated with CP. It has been shown that CP therapy can be beneficial for newly infected COVID-19 patients. Improvement of immune responses and viremia suppression were shown in these patients after treating with CP (Mansourabadi et al., 2020).

Immune checkpoint inhibitors (ICIs)

Different subtypes of T lymphocytes, including cytotoxic T lymphocytes (CD8+ CTLs), helper T cells (CD4+ Th1, Th2, Th17) play crucial roles in maintaining immunity against pathogens like bacteria, viruses, parasites, and fungi, as well as in immunity to cancers. On the other hand, if these responses are not regulated, they can cause acute or chronic inflammation resulting in tissue damage or trigger autoimmune reactions. To this end, the immune system has cells and mediators that modulate and regulate immune responses. These include regulatory T cells (Treg), M2-type macrophages, regulatory cytokines (such as IL-10 and TGF-β), myeloid-derived suppressor cells (MDSCs), immune checkpoint molecules including cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), T-cell immunoglobulin-3 (TIM-3), programmed cell death protein 1 (PD-1), T-cell immunoglobulin and ITIM domain (TIGIT), and lymphocyte activation gene-3 (LAG-3). The elevated levels of these molecules are found in chronic inflammation and cancer as a mechanism for suppressing the immune system. Therefore, targeting regulatory molecules can be considered as an effective therapeutic approach in the treatment of these disorders (Pauken and Wherry, 2015; Butt and Mills, 2014).

ICIs in cancer

Several types of ICIs have been approved for use in humans with cancer. ICIs are mainly monoclonal antibodies that target checkpoint molecules and inhibit their interaction with relevant ligands. So, therapy using ICIs can lead to improving tumor-specific immune responses (Ai and Curran, 2015).

Ipilimumab, a mAb targeting CTLA4, was approved for use in patients with metastatic melanoma, which results in increasing overall survival of patients (Hodi et al., 2010). Using anti-PD-1 and anti-PD-L1 (programmed cell death protein 1 ligand) monoclonal antibodies showed remarkable results in patients with melanoma and non-small cell lung cancer (NSCLC). Pembrolizumab, a mAb targeting the PD-1 molecule, has been approved for the treatment of melanoma (Robert et al., 2014; Magistrelli et al., 1999). Another PD-1 inhibitor, nivolumab, has been approved for use in patients with melanoma, renal cancer, and NSCLC (Callahan et al., 2016). Atezolizumab is a mAb targeting PD-L1 and has been approved for the treatment of bladder cancer. Anti-PD-1 therapy has also demonstrated a considerable effect in the treatment of head and neck, breast, ovarian, and gastric malignancies (Callahan et al., 2016). Moreover, several clinical trials are ongoing to evaluate the effectiveness of mAbs against other immune checkpoint molecules such as LAG-3, TIGIT, and TIM-3, especially in melanoma, breast cancer, renal cancer, and other metastatic solid tumors.

ICIs in infectious diseases

Pathogens can take advantage of immunological checkpoints to suppress host-protective antigen-specific immune responses. T-cell exhaustion is more common in chronic infections than in acute infections, which are generally quickly eliminated by the immune system. Acute lymphocytic choriomeningitis virus (LCMV) infections result in strong activation of pathogen-specific CD8⁺ T lymphocytes. However, continuous viral antigen exposure during chronic LCMV infection causes T-cell reprogramming, leading to elevated PD-1 expression and T-cell exhaustion (Barber et al., 2006). Despite the fact that numerous molecular mechanisms have been involved in the development of T-cell exhaustion, continuous antigen exposure appears to be the primary cause of this event (Schietinger et al., 2016). Targeting immune checkpoints has been shown to be effective in improving T cell function in a variety of chronic infections, such as HIV, hepatitis B, and hepatitis C. Elevated levels of PD-1 has been shown on HIV-specific and Hepatitis B (HBV)-specific CD8⁺ T lymphocytes which are associated with disease progression (Day et al., 2006; Peng et al., 2008). In addition, ex-vivo inhibition of PD-L1 has resulted in increasing IFN- γ production by HIV-specific CD8⁺ T cells, leading to enhanced T cell responses (Day et al., 2006; Petrovas et al., 2006). Increased levels of TIGIT have also been found on HIV-specific T cells and on T cells of SIV-infected macaques, correlating with PD-1 expression. Therefore, targeting both TIGIT and PD-1 may remarkably restore T cell functions (Chew et al., 2016). It has also been indicated that the increased expression of PD-1 on HBV-specific CD8⁺ T cells is associated with viral load and there is evidence supporting the effectiveness of targeting PD-1 or TIM-3 in HBV infection (Peng et al., 2008). Ex vivo experiments using PD-1 blocking led to the production of IFN- γ by CD4⁺ T cells (Tang et al., 2016). In accordance with this, ex vivo inhibition of PD-1 in hepatitis C-specific T cells resulted in restoring T cell function (Salem and El-Badawy, 2015).

In addition to viral infections, immunosuppressive cells, especially Tregs, have also been shown to defend against several helminth parasites, including *F. hepatica*, *Schistosoma mansoni*, and *Heligmosomoides polygyrus* (Finlay et al., 2014). Infection with *Leishmania donovani* in mice and *L. Mexicana* in humans leads to increased expression of PD-1 and T cell exhaustion (Joshi et al., 2009; Hernández-Ruiz et al., 2010). *S. japonicum* has been shown to induce the expression of PD-L2 on dendritic cells, resulting in suppressed immune responses (Gao et al., 2013). Targeting CTLA-4 in mice infected with *Leishmania chagasi*, *plasmodium berghei* ANKA, and *L. donovani* and PD-1/PD-L1 blocking in *Toxoplasma gondii* infection, *L. donovani*, and *plasmodium falciparum* were also shown to be effective in restoring T cell responses. Moreover, targeting immune checkpoint molecules could be a promising approach for bacterial infections, including *H. pylori* and *mycobacterium tuberculosis* (Dyck and Mills, 2017).

T cell immunotherapies

T cells as the main arm of the adaptive immune system play a vital role in defense against pathogens, especially intracellular infections, specific antigen recognition, eliminating virus-infected and cancerous cells, and immune system modulation (Steinman, 2012). Today, the use of cellular therapies for the treatment of cancer, autoimmune diseases, and infectious diseases has received much attention (Parida et al., 2015).

Most immunotherapies that have been clinically approved for infectious diseases or immunological disorders can be divided into two main groups:

- Modulating T cell responses through immunomodulating agents: therapeutic cytokines, immune checkpoint inhibitors, bispecific antibodies (BsAbs)
- Cellular therapies: regulatory T cells (Tregs), tumor-infiltrating T cells (TILs), Chimeric antigen receptor T cells (CAR-T cells), CD8⁺ cytotoxic lymphocytes or NK cells

The use of cytokines has previously been discussed in the context of infectious diseases or immunodeficiency. Using IL-2 is one example of using cytokines as an immunomodulatory agent, especially in cancer therapy. IL-2 is produced by activated T cells and is considered as a main growth factor for T cells and NK cells, playing an important role in proliferation, activation, and cell survival. Treatment with low doses of IL-2 results in greater differentiation of Tregs compared to activated T cells and can therefore be effective

in the treatment of autoimmune diseases such as multiple sclerosis, SLE, as well as GVHD (Klatzmann and Abbas, 2015). In contrast, high doses of IL-2 develop and activate CD4⁺ and CD8⁺ T effector cells and NK cells and have been approved for treating metastatic renal cell carcinoma and metastatic melanoma (Fisher et al., 2000; Rosenberg et al., 1998). However, due to the risks of vascular leak syndrome and hypotension, which may be caused by active IL-2 receptors on endothelia, the use of high doses of IL-2 has been restricted.

Bispecific antibodies (BsAbs)

Bispecific antibodies (BsAbs) have two binding sites with a distinct antigen specificity that can bind to the immune cell and the target antigen expressed on the tumor cell at the same time. BsAbs exert their effects by creating a cytolytic synapse between T cell and target cell that facilitates activation of T cells and subsequently lysis of the target cell (Offner et al., 2006). BsAbs have been proposed for decades as a therapy for cancer and inflammatory diseases, but they have only lately begun to achieve success (Fan et al., 2015). Bi-specific T cell engagers (BiTEs), dual-affinity re-targeting antibodies (DARTs), and Tandem Diabodies are all types of BsAbs. Catumaxomab (Removab) was the first bispecific trifunctional medication to be authorized for the treatment of malignant ascites (Linke et al., 2010; Sedykh et al., 2018). Following that, the BiTE blinatumomab received FDA approval for the treatment of relapsed and/or refractory (R/R) acute lymphoblastic leukemia (ALL) (Przepiorka et al., 2015). Studies are currently focusing on the effectiveness of BiTEs for solid tumor malignancies. Because of the effectiveness of bsAbs in cancer immunotherapy, comparable approaches for eliminating pathogen-infected cells have been developed. DARTs have recently been used to induce T cell-mediated cytotoxicity of latently HIV-infected cells. These bsAbs are composed of anti-Env and anti-CD3 arms that bind to HIV-infected cells as well as CD3-expressing polyclonal T cells at the same time. As a result, HIV-infected CD4⁺ T cells can be eliminated in-vitro by CD8⁺ T cells. The in vivo effectiveness of DARTs on the HIV-1 reservoir is unknown (Sloan et al., 2015; Sung et al., 2015). In addition to DARTs, it has been shown that BiTEs that target the HIV-1 envelope protein gp120 and CD4 may exert strong antiviral effects in vitro and ex vivo (Brozy et al., 2018). Moreover, bsAbs have been designed to facilitate effector T cells against HBV- and human cytomegalovirus (CMV)-infected cells in vitro (Meng et al., 2017).

Chimeric antigen receptor (CAR) T cells

T cells can be genetically engineered for therapeutic application to provide unique antigen specificity by incorporating novel synthetic chimeric antigen receptors (CAR) using different ways to guide these cells toward the target. CAR T cells are engineered T cells that consist of unique parts, including scFv that are involved in specific recognition of target cells, a transmembrane and signaling domains that facilitate T cell activation without MHC interaction. Therefore, antigen specificity is associated with a signaling molecule and may be transmitted to recipient effector cells (e.g., T cells, T cells, NK cells) through various vectors. This approach involves several steps, including ex-vivo expansion of peripheral blood T cells obtained from the patient, genetically engineering the T cells to express CAR, and reinfusion of the modified T cells into the patient (Gattinoni et al., 2006).

T cell immunotherapy has shown promising clinical results in the treatment of hematological malignancies, including ALL and lymphoma (Kochenderfer and Rosenberg, 2013; Maude et al., 2014). Tisagenlecleucel and Axicabtagene Ciloleucel, two CD19-targeted CAR T cell treatments, were recently authorized by the FDA (Neelapu et al., 2017; Schuster et al., 2017). Although using CAR T cells in the treatment of solid tumors has been less successful than in hematologic malignancies, research is ongoing to investigate the effectiveness of CAR T cells in solid tumors such as colorectal cancer and breast cancer.

Major advances in oncology have sparked scientific and clinical enthusiasm for utilizing CAR-Ts to treat illnesses other than cancer. While the majority of CAR T cell research has focused on cancer immunotherapy, Kumaresan and colleagues created a fungal-specific CAR T cell (D-CAR) specific for β -1,3-D-glucan. This CAR T cell was enabled to kill *Aspergillus fumigatus* in vitro and in vivo (Kumaresan et al., 2014).

In a study by Krebs et al., a CAR T cell has been designed (S-CARs) against envelope proteins of HBV. Treating mice with S-CARs resulted in reducing virions in the blood as well as decreasing replicative forms of HBV DNA (Festag et al., 2019).

In another study by Kruse et al., a CAR T cell (anti-HBs-G4m CAR-T cells) specific to HBsAg was designed and its effectiveness was assessed in vitro and in a human liver chimeric mouse model. This CAR T cell was enabled to recognize HBV-infected cells in vitro and decrease HBV-DNA and HBsAg levels in vivo (Kruse et al., 2018).

CAR T cells targeting HCV E2 glycoprotein were designed by Sautto et al. These anti-HCV/E2 CAR-T cells exhibited significant cytotoxicity against HCV-infected cells (Sautto et al., 2016). The efficiency of CAR T cells against M2e protein of Influenza A virus was evaluated in vitro and in vivo by Talbot et al. This CAR T cell leads to decreasing viral titer in murine lungs (Talbot et al., 2013).

The effectiveness of CAR T cells against human immunodeficiency virus (HIV) has been evaluated in several studies. gp120 is considered as the main target for designing CAR T cells against infected cells (Deeks et al., 2002). In vitro studies indicated that CAR T cells can inhibit viral replication in infected cells and increase the death of infected cells. The effectiveness of targeting gp41 is also reported in some studies. In addition, the efficiency of the new generation of anti-HIV CARs that are based on broadly neutralizing antibodies (BNAbs) was shown in several studies, resulting in significant anti-viral activity in vitro through killing of infected cells (Ali et al., 2016; Liu et al., 2016a,b; Liu et al., 2015).
